Survival Analysis: Introduction

Survival Analysis typically focuses on time to event data. In the most general sense, it consists of techniques for positive-valued random variables, such as

- time to death
- time to onset (or relapse) of a disease
- length of stay in a hospital
- duration of a strike
- money paid by health insurance
- viral load measurements
- time to finishing a doctoral dissertation!

Kinds of survival studies include:

- clinical trials
- prospective cohort studies
- retrospective cohort studies
- retrospective correlative studies

Typically, survival data are not fully observed, but rather are censored.
In this course, we will:

- describe survival data
- compare survival of several groups
- explain survival with covariates
- design studies with survival endpoints

Some knowledge of discrete data methods will be useful, since analysis of the “time to event” uses information from the discrete (i.e., binary) outcome of whether the event occurred or not.

**Some Definitions and notation**

**Failure time random variables** are always **non-negative**. That is, if we denote the failure time by $T$, then $T \geq 0$.

$T$ can either be **discrete** (taking a finite set of values, e.g. $a_1, a_2, \ldots, a_n$) or **continuous** (defined on $(0, \infty)$).

A random variable $X$ is called a **censored failure time random variable** if $X = \min(T, U)$, where $U$ is a non-negative censoring variable.

**In order to define a failure time random variable, we need:**

1. an unambiguous **time origin**
   (e.g. randomization to clinical trial, purchase of car)

2. a **time scale**
   (e.g. real time (days, years), mileage of a car)

3. definition of the **event**
   (e.g. death, need a new car transmission)
Illustration of survival data

- $X$ = event
- $\bullet$ = censored observation

Study opens

Study closes
The illustration of survival data on the previous page shows several features which are typically encountered in analysis of survival data:

- individuals do not all enter the study at the same time
- when the study ends, some individuals still haven’t had the event yet
- other individuals drop out or get lost in the middle of the study, and all we know about them is the last time they were still “free” of the event

The first feature is referred to as “staggered entry”

The last two features relate to “censoring” of the failure time events.
Types of censoring:

- **Right-censoring:**

  only the r.v. $X_i = \min(T_i, U_i)$ is observed due to
  - loss to follow-up
  - drop-out
  - study termination

  We call this right-censoring because the true unobserved event is to the right of our censoring time; i.e., all we know is that the event has not happened at the end of follow-up.

  In addition to observing $X_i$, we also get to see the **failure indicator**:

  $$\delta_i = \begin{cases} 
  1 & \text{if } T_i \leq U_i \\
  0 & \text{if } T_i > U_i 
  \end{cases}$$

  Some software packages instead assume we have a **censoring indicator**:

  $$c_i = \begin{cases} 
  0 & \text{if } T_i \leq U_i \\
  1 & \text{if } T_i > U_i 
  \end{cases}$$

  Right-censoring is the most common type of censoring assumption we will deal with in survival analysis.
• **Left-censoring**

Can only observe \( Y_i = \max(T_i, U_i) \) and the failure indicators:

\[
\delta_i = \begin{cases} 
1 & \text{if } U_i \leq T_i \\
0 & \text{if } U_i > T_i 
\end{cases}
\]

e.g. (Miller) study of age at which African children learn a task. Some already knew (left-censored), some learned during study (exact), some had not yet learned by end of study (right-censored).

• **Interval-censoring**

Observe \((L_i, R_i)\) where \( T_i \in (L_i, R_i) \)

Ex. 1: Time to prostate cancer, observe longitudinal PSA measurements

Ex. 2: Time to undetectable viral load in AIDS studies, based on measurements of viral load taken at each clinic visit

Ex. 3: Detect recurrence of colon cancer after surgery. Follow patients every 3 months after resection of primary tumor.
Independent vs informative censoring

- We say censoring is **independent** (non-informative) if $U_i$ is independent of $T_i$.
  - **Ex. 1** If $U_i$ is the planned end of the study (say, 2 years after the study opens), then it is usually independent of the event times.
  - **Ex. 2** If $U_i$ is the time that a patient drops out of the study because he/she got much sicker and/or had to discontinue taking the study treatment, then $U_i$ and $T_i$ are probably not independent.

An individual censored at $U$ should be representative of all subjects who survive to $U$.

This means that censoring at $U$ *could* depend on prognostic characteristics measured at baseline, but that among all those with the same baseline characteristics, the probability of censoring prior to or at time $U$ should be the same.

- Censoring is considered **informative** if the distribution of $U_i$ contains any information about the parameters characterizing the distribution of $T_i$. 
Suppose we have a sample of observations on $n$ people:

$$(T_1, U_1), (T_2, U_2), \ldots, (T_n, U_n)$$

There are three main types of (right) censoring times:

- **Type I**: All the $U_i$’s are the same
  
e.g. animal studies, all animals sacrificed after 2 years

- **Type II**: $U_i = T_{(r)}$, the time of the $r$th failure.
  
e.g. animal studies, stop when 4/6 have tumors

- **Type III**: the $U_i$’s are random variables, $\delta_i$’s are failure indicators:

\[
\delta_i = \begin{cases} 
1 & \text{if } T_i \leq U_i \\
0 & \text{if } T_i > U_i 
\end{cases}
\]

Type I and Type II are called *singly* censored data, Type III is called *randomly* censored (or sometimes *progressively* censored).
Some example datasets:

Example A. Duration of nursing home stay
(Morris et al., Case Studies in Biometry, Ch 12)

The National Center for Health Services Research studied 36 for-profit nursing homes to assess the effects of different financial incentives on length of stay. “Treated” nursing homes received higher per diems for Medicaid patients, and bonuses for improving a patient’s health and sending them home.

Study included 1601 patients admitted between May 1, 1981 and April 30, 1982.

Variables include:

- LOS - Length of stay of a resident (in days)
- AGE - Age of a resident
- RX - Nursing home assignment (1: bonuses, 0: no bonuses)
- GENDER - Gender (1: male, 0: female)
- MARRIED - (1: married, 0: not married)
- HEALTH - Health status (2: second best, 5: worst)
- CENSOR - Censoring indicator (1: censored, 0: discharged)

First few lines of data:

37 86 1 0 0 2 0
61 77 1 0 0 4 0
Example B. Fecundability

Women who had recently given birth were asked to recall how long it took them to become pregnant, and whether or not they smoked during that time. The outcome of interest (summarized below) is time to pregnancy (measured in menstrual cycles).

19 subjects were not able to get pregnant after 12 months.

<table>

Example C: MAC Prevention Clinical Trial

ACTG 196 was a randomized clinical trial to study the effects of combination regimens on prevention of MAC (*mycobacterium avium complex*), one of the most common opportunistic infections in AIDS patients.

The **treatment regimens** were:

- clarithromycin (new)
- rifabutin (standard)
- clarithromycin plus rifabutin

Other characteristics of trial:

- Patients enrolled between April 1993 and February 1994
- Follow-up ended August 1995
- In February 1994, rifabutin dosage was reduced from 3 pills/day (450mg) to 2 pills/day (300mg) due to concern over **uveitis**\(^1\)

The main intent-to-treat analysis compared the 3 treatment arms without adjusting for this change in dosage.

---

\(^1\) *Uveitis* is an adverse experience resulting in inflammation of the uveal tract in the eyes (about 3-4% of patients reported uveitis).
Example D: HMO Study of HIV-related Survival

This is hypothetical data used by Hosmer & Lemeshow (described on pages 2-17) containing 100 observations on HIV+ subjects belonging to an Health Maintenance Organization (HMO). The HMO wants to evaluate the survival time of these subjects. In this hypothetical dataset, subjects were enrolled from January 1, 1989 until December 31, 1991. Study follow up then ended on December 31, 1995.

Variables:

- **ID**: Subject ID (1-100)
- **TIME**: Survival time in months
- **ENTDATE**: Entry date
- **ENDDATE**: Date follow-up ended due to death or censoring
- **CENSOR**: Death Indicator (1=death, 0=censor)
- **AGE**: Age of subject in years
- **DRUG**: History of IV Drug Use (0=no,1=yes)

This dataset is used by Hosmer & Lemeshow to motivate some concepts in survival analysis in Chap. 1 of their book.
Example E: UMARU Impact Study (UIS)

This dataset comes from the University of Massachusetts AIDS Research Unit (UMARU) IMPACT Study, a 5-year collaborative research project comprised of two concurrent randomized trials of residential treatment for drug abuse.

(1) **Program A:** Randomized 444 subjects to a 3- or 6-month program of health education and relapse prevention. Clients were taught to recognize “high-risk” situations that are triggers to relapse, and taught skills to cope with these situations without using drugs.

(2) **Program B:** Randomized 184 participants to a 6- or 12-month program with highly structured life-style in a communal living setting.

**Variables:**

<table>

Example F: Atlantic Halibut Survival Times

One conservation measure suggested for trawl fishing is a minimum size limit for halibut (32 inches). However, this size limit would only be effective if captured fish below the limit survived until the time of their release. An experiment was conducted to evaluate the survival rates of halibut caught by trawls or longlines, and to assess other factors which might contribute to survival (duration of trawling, maximum depth fished, size of fish, and handling time).

An article by Smith, Waiwood and Neilson, *Survival Analysis for Size Regulation of Atlantic Halibut* in *Case Studies in Biometry* compares parametric survival models to semi-parametric survival models in evaluating this data.

</table>
More Definitions and Notation

There are several equivalent ways to characterize the probability distribution of a survival random variable. Some of these are familiar; others are special to survival analysis. We will focus on the following terms:

- The density function $f(t)$
- The survivor function $S(t)$
- The hazard function $\lambda(t)$
- The cumulative hazard function $\Lambda(t)$

- Density function (or Probability Mass Function) for discrete r.v.’s
  Suppose that $T$ takes values in $a_1, a_2, \ldots, a_n$.
  $$f(t) = Pr(T = t)$$
  $$= \begin{cases} f_j & \text{if } t = a_j, j = 1, 2, \ldots, n \\ 0 & \text{if } t \neq a_j, j = 1, 2, \ldots, n \end{cases}$$

- Density Function for continuous r.v.’s
  $$f(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} Pr(t \leq T \leq t + \Delta t)$$
• **Survivorship Function**: \( S(t) = P(T \geq t) \).

In other settings, the cumulative distribution function, \( F(t) = P(T \leq t) \), is of interest. In survival analysis, our interest tends to focus on the survival function, \( S(t) \).

**For a continuous random variable:**
\[
S(t) = \int_t^\infty f(u)du
\]

**For a discrete random variable:**
\[
S(t) = \sum_{u \geq t} f(u) \\
= \sum_{a_j \geq t} f(a_j) \\
= \sum_{a_j \geq t} f_j
\]

**Notes:**

• From the definition of \( S(t) \) for a continuous variable, \( S(t) = 1 - F(t) \) as long as \( F(t) \) is absolutely continuous w.r.t the Lebesgue measure. [That is, \( F(t) \) has a density function.]

• For a discrete variable, we have to decide what to do if an event occurs exactly at time \( t \); i.e., does that become part of \( F(t) \) or \( S(t) \)?

• To get around this problem, several books define \( S(t) = Pr(T > t) \), or else define \( F(t) = Pr(T < t) \) (eg. Collett)
• Hazard Function $\lambda(t)$

Sometimes called an *instantaneous failure rate*, the *force of mortality*, or the *age-specific failure rate*.

− **Continuous random variables:**

$$
\lambda(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \frac{Pr(t \leq T < t + \Delta t | T \geq t)}{Pr(T \geq t)}
$$

$$
= \lim_{\Delta t \to 0} \frac{1}{\Delta t} \frac{Pr([t \leq T < t + \Delta t] \cap [T \geq t])}{Pr(T \geq t)}
$$

$$
= \lim_{\Delta t \to 0} \frac{1}{\Delta t} \frac{Pr(t \leq T < t + \Delta t)}{Pr(T \geq t)}
$$

$$
= \frac{f(t)}{S(t)}
$$

− **Discrete random variables:**

$$
\lambda(a_j) \equiv \lambda_j = Pr(T = a_j | T \geq a_j)
$$

$$
= \frac{P(T = a_j)}{P(T \geq a_j)}
$$

$$
= \frac{f(a_j)}{S(a_j)}
$$

$$
= \frac{f(t)}{\sum_{k:a_k \geq a_j} f(a_k)}
$$
• Cumulative Hazard Function \( \Lambda(t) \)

   - Continuous random variables:
     \[
     \Lambda(t) = \int_0^t \lambda(u)du
     \]

   - Discrete random variables:
     \[
     \Lambda(t) = \sum_{k:a_k<t} \lambda_k
     \]
Relationship between $S(t)$ and $\lambda(t)$

We’ve already shown that, for a continuous r.v.

$$\lambda(t) = \frac{f(t)}{S(t)}$$

For a left-continuous survivor function $S(t)$, we can show:

$$f(t) = -S'(t) \quad \text{or} \quad S'(t) = -f(t)$$

We can use this relationship to show that:

$$- \frac{d}{dt} \log S(t) = - \left( \frac{1}{S(t)} \right) S'(t)$$

$$= - \frac{-f(t)}{S(t)}$$

$$= \frac{f(t)}{S(t)}$$

So another way to write $\lambda(t)$ is as follows:

$$\lambda(t) = - \frac{d}{dt} \log S(t)$$
Relationship between $S(t)$ and $\Lambda(t)$:

- **Continuous case:**
  \[
  \Lambda(t) = \int_0^t \lambda(u) du \\
  = \int_0^t \frac{f(u)}{S(u)} du \\
  = \int_0^t -\frac{d}{du} \log S(u) du \\
  = -\log S(t) + \log S(0) \\
  \Rightarrow S(t) = e^{-\Lambda(t)}
  \]

- **Discrete case:**
  Suppose that $a_j < t \leq a_{j+1}$. Then
  \[
  S(t) = P(T \geq a_1, T \geq a_2, \ldots, T \geq a_{j+1}) \\
  = P(T \geq a_1)P(T \geq a_2|T \geq a_1) \cdots P(T \geq a_{j+1}|T \geq a_j) \\
  = (1 - \lambda_1) \times \cdots \times (1 - \lambda_j) \\
  = \prod_{k:a_k < t} (1 - \lambda_k)
  \]
  Cox defines $\Lambda(t) = \sum_{k:a_k < t} \log(1 - \lambda_k)$ so that $S(t) = e^{-\Lambda(t)}$ in the discrete case, as well.
Measuring Central Tendency in Survival

- **Mean survival** - call this $\mu$

  $\mu = \int_0^\infty u f(u) du$ for continuous $T$

  $= \sum_{j=1}^n a_j f_j$ for discrete $T$

- **Median survival** - call this $\tau$, is defined by

  $S(\tau) = 0.5$

  Similarly, any other percentile could be defined.

  In practice, we don’t usually hit the median survival at exactly one of the failure times. In this case, the estimated median survival is the *smallest* time $\tau$ such that

  $\hat{S}(\tau) \leq 0.5$
Some hazard shapes seen in applications:

- **increasing**
  e.g. aging after 65

- **decreasing**
  e.g. survival after surgery

- **bathtub**
  e.g. age-specific mortality

- **constant**
  e.g. survival of patients with advanced chronic disease
Estimating the survival or hazard function

We can estimate the survival (or hazard) function in two ways:

- by specifying a parametric model for $\lambda(t)$ based on a particular density function $f(t)$
- by developing an empirical estimate of the survival function (i.e., non-parametric estimation)

If no censoring:
The empirical estimate of the survival function, $\hat{S}(t)$, is the proportion of individuals with event times greater than $t$.

With censoring:
If there are censored observations, then $\hat{S}(t)$ is not a good estimate of the true $S(t)$, so other non-parametric methods must be used to account for censoring (life-table methods, Kaplan-Meier estimator)
Some Parametric Survival Distributions

- The **Exponential** distribution (1 parameter)

\[
\begin{align*}
    f(t) &= \lambda e^{-\lambda t} \text{ for } t \geq 0 \\
    S(t) &= \int_t^\infty f(u) \, du \\
        &= e^{-\lambda t} \\
    \lambda(t) &= \frac{f(t)}{S(t)} \\
        &= \lambda \quad \text{constant hazard!}
\end{align*}
\]

\[
\begin{align*}
    \Lambda(t) &= \int_0^t \lambda(u) \, du \\
        &= \int_0^t \lambda \, du \\
        &= \lambda t
\end{align*}
\]

**Check:** Does \( S(t) = e^{-\Lambda(t)} \)?

**median:** solve \( 0.5 = S(\tau) = e^{-\lambda \tau} \):

\[
\Rightarrow \tau = \frac{-\log(0.5)}{\lambda}
\]

**mean:**

\[
\int_0^\infty u \lambda e^{-\lambda u} \, du = \frac{1}{\lambda}
\]
• The **Weibull** distribution (2 parameters)
  Generalizes exponential:
  \[
  S(t) = e^{-\lambda t^\kappa}
  \]
  \[
  f(t) = \frac{-d}{dt} S(t) = \kappa \lambda t^{\kappa-1} e^{-\lambda t^\kappa}
  \]
  \[
  \lambda(t) = \kappa \lambda t^{\kappa-1}
  \]
  \[
  \Lambda(t) = \int_0^t \lambda(u)du = \lambda t^\kappa
  \]

  \(\lambda\) - the *scale* parameter
  \(\kappa\) - the *shape* parameter

  The Weibull distribution is convenient because of its simple form. It includes several hazard shapes:
  \[
  \kappa = 1 \rightarrow \text{constant hazard}
  \]
  \[
  0 < \kappa < 1 \rightarrow \text{decreasing hazard}
  \]
  \[
  \kappa > 1 \rightarrow \text{increasing hazard}
  \]
• **Rayleigh** distribution
  Another 2-parameter generalization of exponential:
  \[ \lambda(t) = \lambda_0 + \lambda_1 t \]

• **compound exponential**
  \[ T \sim \exp(\lambda), \lambda \sim g \]
  \[ f(t) = \int_0^\infty \lambda e^{-\lambda t} g(\lambda) d\lambda \]

• **log-normal, log-logistic:**
  Possible distributions for \( T \) obtained by specifying for \( \log T \) any convenient family of distributions, e.g.
  \[ \log T \sim \text{normal (non-monotone hazard)} \]
  \[ \log T \sim \text{logistic} \]
Why use one versus another?

- technical convenience for estimation and inference

- explicit simple forms for $f(t)$, $S(t)$, and $\lambda(t)$.

- qualitative shape of hazard function

One can usually distinguish between a one-parameter model (like the exponential) and two-parameter (like Weibull or log-normal) in terms of the adequacy of fit to a dataset.

Without a lot of data, it may be hard to distinguish between the fits of various 2-parameter models (i.e., Weibull vs log-normal)
Plots of estimates of $S(t)$
Based on KM, exponential, Weibull, and log-normal for study of protease inhibitors in AIDS patients (ACTG 320)
Plots of estimates of $S(t)$
Based on KM, exponential, Weibull, and log-normal
for study of protease inhibitors in AIDS patients
(ACTG 320)
Plots of estimates of $S(t)$
Based on KM, exponential, Weibull, and log-normal
for study of protease inhibitors in AIDS patients
(ACTG 320)
Next we will discuss the most famous non-parametric approach for estimating the survival distribution, called the Kaplan-Meier estimator.

To motivate the derivation of this estimator, we will first consider a set of survival times where there is no censoring.

The following are times to relapse (weeks) for 21 leukemia patients receiving control treatment (Table 1.1 of Cox & Oakes):

1, 1, 2, 2, 3, 4, 4, 5, 5, 8, 8, 8, 8, 11, 11, 12, 12, 15, 17, 22, 23

How would we estimate $S(10)$, the probability that an individual survives to time 10 or later?

What about $\tilde{S}(8)$? Is it $\frac{12}{21}$ or $\frac{8}{21}$?
Let’s construct a table of $\hat{S}(t)$:

<table>
<thead>
<tr>
<th>Values of $t$</th>
<th>$\hat{S}(t)$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$t \leq 1$</td>
<td>$21/21=1.000$</td>
</tr>
<tr>
<td>$1 &lt; t \leq 2$</td>
<td>$19/21=0.905$</td>
</tr>
<tr>
<td>$2 &lt; t \leq 3$</td>
<td>$17/21=0.809$</td>
</tr>
<tr>
<td>$3 &lt; t \leq 4$</td>
<td></td>
</tr>
<tr>
<td>$4 &lt; t \leq 5$</td>
<td></td>
</tr>
<tr>
<td>$5 &lt; t \leq 8$</td>
<td></td>
</tr>
<tr>
<td>$8 &lt; t \leq 11$</td>
<td></td>
</tr>
<tr>
<td>$11 &lt; t \leq 12$</td>
<td></td>
</tr>
<tr>
<td>$12 &lt; t \leq 15$</td>
<td></td>
</tr>
<tr>
<td>$15 &lt; t \leq 17$</td>
<td></td>
</tr>
<tr>
<td>$17 &lt; t \leq 22$</td>
<td></td>
</tr>
<tr>
<td>$22 &lt; t \leq 23$</td>
<td></td>
</tr>
</tbody>
</table>

**Empirical Survival Function:**

When there is no censoring, the general formula is:

$$\hat{S}(t) = \frac{\# \text{ individuals with } T \geq t}{\text{total sample size}}$$
In most software packages, the survival function is evaluated just after time $t$, i.e., at $t^+$. In this case, we only count the individuals with $T > t$.

Example for leukemia data (control arm):

![Empirical Survivor Function - Control Arm](image)

<table>
<thead>
<tr>
<th>Censored</th>
<th>Failed</th>
<th>Total</th>
<th>Median</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>21</td>
<td>21</td>
<td>8.0</td>
</tr>
</tbody>
</table>
Stata Commands for Survival Estimation

Does anyone have a guess regarding how to calculate the standard error of the estimated survival?

\[ \hat{S}(8^+) = P(T > 8) = \frac{8}{21} = 0.381 \]

(at \( t = 8^+ \), we count the 4 events at time=8 as already having failed)

\[ se[\hat{S}(8^+)] = 0.106 \]

Estimating the Survival Function

One-sample nonparametric methods:

We will consider three methods for estimating a survivorship function

\[ S(t) = Pr(T \geq t) \]

without resorting to parametric methods:

1. **Kaplan-Meier**

2. **Life-table** (Actuarial Estimator)

3. via the **Cumulative hazard estimator**
(1) The Kaplan-Meier Estimator

The Kaplan-Meier (or KM) estimator is probably the most popular approach. It can be justified from several perspectives:

- product limit estimator
- likelihood justification
- redistribute to the right estimator

We will start with an intuitive motivation based on conditional probabilities, then review some of the other justifications.
Motivation:

First, consider an example where there is no censoring.

The following are times of remission (weeks) for 21 leukemia patients receiving control treatment (Table 1.1 of Cox & Oakes):

1, 1, 2, 2, 3, 4, 4, 5, 5, 8, 8, 8, 8, 11, 11, 12, 12, 15, 17, 22, 23

How would we estimate \( \hat{S}(10) \), the probability that an individual survives to time 10 or later?

What about \( \hat{S}(8) \)? Is it \( \frac{12}{21} \) or \( \frac{8}{21} \)?

Let’s construct a table of \( \hat{S}(t) \):

<table>
<thead>
<tr>
<th>Values of t</th>
<th>( \hat{S}(t) )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( t \leq 1 )</td>
<td>21/21=1.000</td>
</tr>
<tr>
<td>( 1 &lt; t \leq 2 )</td>
<td>19/21=0.905</td>
</tr>
<tr>
<td>( 2 &lt; t \leq 3 )</td>
<td>17/21=0.809</td>
</tr>
<tr>
<td>( 3 &lt; t \leq 4 )</td>
<td></td>
</tr>
<tr>
<td>( 4 &lt; t \leq 5 )</td>
<td></td>
</tr>
<tr>
<td>( 5 &lt; t \leq 8 )</td>
<td></td>
</tr>
<tr>
<td>( 8 &lt; t \leq 11 )</td>
<td></td>
</tr>
<tr>
<td>( 11 &lt; t \leq 12 )</td>
<td></td>
</tr>
<tr>
<td>( 12 &lt; t \leq 15 )</td>
<td></td>
</tr>
<tr>
<td>( 15 &lt; t \leq 17 )</td>
<td></td>
</tr>
<tr>
<td>( 17 &lt; t \leq 22 )</td>
<td></td>
</tr>
<tr>
<td>( 22 &lt; t \leq 23 )</td>
<td></td>
</tr>
</tbody>
</table>
Empirical Survival Function:
When there is no censoring, the general formula is:

\[ \tilde{S}(t) = \frac{\# \text{ individuals with } T \geq t}{\text{total sample size}} \]

Example for leukemia data (control arm):

![Empirical Survivor Function – Control Arm](image)

<table>
<thead>
<tr>
<th>Censored</th>
<th>Failed</th>
<th>Total</th>
<th>Median</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>21</td>
<td>21</td>
<td>8.0</td>
</tr>
</tbody>
</table>
What if there is censoring?

Consider the treated group from Table 1.1 of Cox and Oakes:

\[ 6^+, 6, 6, 6, 7, 9^+, 10^+, 10, 11^+, 13, 16, 17^+ \]
\[ 19^+, 20^+, 22, 23, 25^+, 32^+, 32^+, 34^+, 35^+ \]

[Note: times with + are right censored]

We know \( S(6) = 21/21 \), because everyone survived at least until time 6 or greater. But, we can’t say \( S(7) = 17/21 \), because we don’t know the status of the person who was censored at time 6.

In a 1958 paper in the *Journal of the American Statistical Association*, Kaplan and Meier proposed a way to nonparametrically estimate \( S(t) \), even in the presence of censoring. The method is based on the ideas of conditional probability.
A quick review of conditional probability:

**Conditional Probability:** Suppose A and B are two events. Then,

\[ P(A|B) = \frac{P(A \cap B)}{P(B)} \]

**Multiplication law of probability:** can be obtained from the above relationship, by multiplying both sides by \( P(B) \):

\[ P(A \cap B) = P(A|B)P(B) \]

**Extension to more than 2 events:**
Suppose \( A_1, A_2...A_k \) are k different events. Then, the probability of all k events happening together can be written as a product of conditional probabilities:

\[ P(A_1 \cap A_2... \cap A_k) = P(A_k|A_{k-1} \cap ... \cap A_1) \times \]
\[ \times P(A_{k-1}|A_{k-2} \cap ... \cap A_1) \]
\[ \times ... \]
\[ \times P(A_2|A_1) \]
\[ \times P(A_1) \]
Now, let’s apply these ideas to estimate $S(t)$:

Suppose $a_k < t \leq a_{k+1}$. Then

$$S(t) = P(T \geq a_{k+1})$$

$$= P(T \geq a_1, T \geq a_2, \ldots, T \geq a_{k+1})$$

$$= P(T \geq a_1) \times \prod_{j=1}^{k} P(T \geq a_{j+1}|T \geq a_j)$$

$$= \prod_{j=1}^{k} [1 - P(T = a_j|T \geq a_j)]$$

$$= \prod_{j=1}^{k} [1 - \lambda_j]$$

so

$$\hat{S}(t) \approx \prod_{j=1}^{k} \left(1 - \frac{d_j}{r_j}\right)$$

$$= \prod_{j:a_j<t} \left(1 - \frac{d_j}{r_j}\right)$$

$d_j$ is the number of deaths at $a_j$

$r_j$ is the number at risk at $a_j$
Intuition behind the Kaplan-Meier Estimator

Think of dividing the observed timespan of the study into a series of fine intervals so that there is a separate interval for each time of death or censoring:

\[
\begin{array}{cccccc}
D & | & C & | & C & | D & D & D
\end{array}
\]

Using the law of conditional probability,

\[
Pr(T \geq t) = \prod_j Pr(\text{survive } j\text{-th interval } I_j \mid \text{survived to start of } I_j)
\]

where the product is taken over all the intervals including or preceding time \( t \).
4 possibilities for each interval:

1. **No events (death or censoring)** - conditional probability of surviving the interval is 1

2. **Censoring** - assume they survive to the end of the interval, so that the conditional probability of surviving the interval is 1

3. **Death, but no censoring** - conditional probability of *not* surviving the interval is \# deaths (d) divided by \# ‘at risk’ (r) at the beginning of the interval. So the conditional probability of surviving the interval is \(1 - (d/r)\).

4. **Tied deaths and censoring** - assume censorings last to the end of the interval, so that conditional probability of surviving the interval is still \(1 - (d/r)\).

**General Formula for \(j\)th interval:**

It turns out we can write a general formula for the conditional probability of surviving the \(j\)-th interval that holds for all 4 cases:

\[
1 - \frac{d_j}{r_j}
\]
We could use the same approach by grouping the event times into intervals (say, one interval for each month), and then counting up the number of deaths (events) in each to estimate the probability of surviving the interval (this is called the lifetable estimate).

However, the assumption that those censored last until the end of the interval wouldn’t be quite accurate, so we would end up with a cruder approximation.

As the intervals get finer and finer, the approximations made in estimating the probabilities of getting through each interval become smaller and smaller, so that the estimator converges to the true $S(t)$.

This intuition clarifies why an alternative name for the KM is the product limit estimator.
The Kaplan-Meier estimator of the survivorship function (or survival probability) \( S(t) = Pr(T \geq t) \) is:

\[
\hat{S}(t) = \prod_{j: \tau_j < t} \left( 1 - \frac{d_j}{r_j} \right)
\]

where

- \( \tau_1, \ldots, \tau_K \) is the set of K distinct death times observed in the sample
- \( d_j \) is the number of deaths at \( \tau_j \)
- \( r_j \) is the number of individuals “at risk” right before the \( j \)-th death time (everyone dead or censored at or after that time).
- \( c_j \) is the number of censored observations between the \( j \)-th and \((j + 1)\)-st death times. Censoring tied at \( \tau_j \) are included in \( c_j \)

**Note: two useful formulas are:**

1. \( r_j = r_{j-1} - d_{j-1} - c_{j-1} \)
2. \( r_j = \sum_{l \geq j} (c_l + d_l) \)
Calculating the KM - Cox and Oakes example

Make a table with a row for every death or censoring time:

<table>
<thead>
<tr>
<th>$\tau_j$</th>
<th>$d_j$</th>
<th>$c_j$</th>
<th>$r_j$</th>
<th>$1 - (d_j/r_j)$</th>
<th>$\hat{S}(\tau_j^+)$</th>
</tr>
</thead>
<tbody>
<tr>
<td>6</td>
<td>3</td>
<td>1</td>
<td>21</td>
<td>$\frac{18}{21} = 0.857$</td>
<td></td>
</tr>
<tr>
<td>7</td>
<td>1</td>
<td>0</td>
<td>17</td>
<td></td>
<td></td>
</tr>
<tr>
<td>9</td>
<td>0</td>
<td>1</td>
<td>16</td>
<td></td>
<td></td>
</tr>
<tr>
<td>10</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>11</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>13</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>16</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>17</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>19</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>20</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>22</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>23</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Note that:

- $\hat{S}(t^+)$ only changes at death (failure) times
- $\hat{S}(t^+)$ is 1 up to the first death time
- $\hat{S}(t^+)$ only goes to 0 if the last event is a death
Note: most statistical software packages summarize the KM survival function at $\tau^+_j$, i.e., just after the time of the $j$-th failure.

In other words, they provide $\hat{S}(\tau^+_j)$. 

When there is no censoring, the empirical survival estimate would then be:

$$\hat{S}(t^+) = \frac{\# \text{ individuals with } T > t}{\text{total sample size}}$$
Output from STATA KM Estimator:

failure time: weeks
failure/censor: remiss

Two Other Justifications for KM Estimator

I. Likelihood-based derivation (Cox and Oakes)

For a discrete failure time variable, define:

\[ d_j \] number of failures at \( a_j \)
\[ r_j \] number of individuals at risk at \( a_j \)
   (including those censored at \( a_j \)).
\[ \lambda_j \] Pr(death) in \( j \)-th interval
   (conditional on survival to start of interval)

The likelihood is that of \( g \) independent binomials:

\[
L(\lambda) = \prod_{j=1}^{g} \lambda_j^{d_j} (1 - \lambda_j)^{r_j - d_j}
\]

Therefore, the maximum likelihood estimator of \( \lambda_j \) is:

\[ \hat{\lambda}_j = \frac{d_j}{r_j} \]

Now we plug in the MLE’s of \( \lambda \) to estimate \( S(t) \):

\[
\hat{S}(t) = \prod_{j:a_j<t} (1 - \hat{\lambda}_j)
\]

\[
= \prod_{j:a_j<t} \left(1 - \frac{d_j}{r_j}\right)
\]
II. Redistribute to the right justification
(Efron, 1967)

In the absence of censoring, $\hat{S}(t)$ is just the proportion of individuals with $T \geq t$. The idea behind Efron’s approach is to spread the contributions of censored observations out over all the possible times to their right.

**Algorithm:**

- Step (1): arrange the $n$ observed times (deaths or censorings) in increasing order. If there are ties, put censored after deaths.
- Step (2): Assign weight $(1/n)$ to each time.
- Step (3): Moving from left to right, each time you encounter a censored observation, distribute its mass to all times to its right.
- Step (4): Calculate $\hat{S}_j$ by subtracting the final weight for time $j$ from $\hat{S}_{j-1}$
Example of “redistribute to the right” algorithm

Consider the following event times:

\[2, 2.5+, 3, 3, 4, 4.5+, 5, 6, 7\]

The algorithm goes as follows:

<table>
<thead>
<tr>
<th>Times</th>
<th>Step 2</th>
<th>Step 3a</th>
<th>Step 3b</th>
<th>(\hat{S}(\tau_j))</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
<td>1/9=0.11</td>
<td></td>
<td></td>
<td>0.889</td>
</tr>
<tr>
<td>2.5+</td>
<td>1/9=0.11</td>
<td>0</td>
<td></td>
<td>0.889</td>
</tr>
<tr>
<td>3</td>
<td>2/9=0.22</td>
<td>0.25</td>
<td></td>
<td>0.635</td>
</tr>
<tr>
<td>4</td>
<td>1/9=0.11</td>
<td>0.13</td>
<td></td>
<td>0.508</td>
</tr>
<tr>
<td>4.5+</td>
<td>1/9=0.11</td>
<td>0.13</td>
<td>0</td>
<td>0.508</td>
</tr>
<tr>
<td>5</td>
<td>1/9=0.11</td>
<td>0.13</td>
<td>0.17</td>
<td>0.339</td>
</tr>
<tr>
<td>6</td>
<td>1/9=0.11</td>
<td>0.13</td>
<td>0.17</td>
<td>0.169</td>
</tr>
<tr>
<td>7</td>
<td>1/9=0.11</td>
<td>0.13</td>
<td>0.17</td>
<td>0.000</td>
</tr>
</tbody>
</table>

This comes out the same as the product limit approach.
Properties of the KM estimator

In the case of no censoring:

\[ \hat{S}(t) = \tilde{S}(t) = \frac{\# \text{ deaths at } t \text{ or greater}}{n}, \]

where \( n \) is the number of individuals in the study.

This is just like an estimated probability from a binomial distribution, so we have:

\[ \hat{S}(t) \approx \mathcal{N}(S(t), S(t)[1 - S(t)]/n) \]

How does censoring affect this?

- \( \hat{S}(t) \) is still approximately normal
- The mean of \( \hat{S}(t) \) converges to the true \( S(t) \)
- The variance is a bit more complicated (since the denominator \( n \) includes some censored observations).

Once we get the variance, then we can construct (pointwise) \((1 - \alpha)\%\) confidence intervals (NOT bands) about \( \hat{S}(t) \):

\[ \hat{S}(t) \pm z_{1-\alpha/2} \text{se}[\hat{S}(t)] \]
Greenwood’s formula (Collett 2.1.3)

We can think of the KM estimator as

\[ \hat{S}(t) = \prod_{j: r_j < t} (1 - \hat{\lambda}_j) \]

where \( \hat{\lambda}_j = \frac{d_j}{r_j} \).

Since the \( \hat{\lambda}_j \)'s are just binomial proportions, we can apply standard likelihood theory to show that each \( \hat{\lambda}_j \) is approximately normal, with mean the true \( \lambda_j \), and

\[ \text{var}(\hat{\lambda}_j) \approx \frac{\hat{\lambda}_j(1 - \hat{\lambda}_j)}{r_j} \]

Also, the \( \hat{\lambda}_j \)'s are independent in large enough samples.

Since \( \hat{S}(t) \) is a function of the \( \lambda_j \)'s, we can estimate its variance using the delta method:

**Delta method:** If \( Y \) is normal with mean \( \mu \) and variance \( \sigma^2 \), then \( g(Y) \) is approximately normally distributed with mean \( g(\mu) \) and variance \( [g'(\mu)]^2 \sigma^2 \).
Two specific examples of the delta method:

(A) $Z = \log(Y)$

then $Z \sim N \left[ \log(\mu), \left( \frac{1}{\mu} \right)^2 \sigma^2 \right]$

(B) $Z = \exp(Y)$

then $Z \sim N \left[ e^\mu, [e^\mu]^2 \sigma^2 \right]$

The examples above use the following results from calculus:

$$\frac{d}{dx} \log u = \frac{1}{u} \left( \frac{du}{dx} \right)$$

$$\frac{d}{dx} e^u = e^u \left( \frac{du}{dx} \right)$$
Greenwood’s formula (continued)

Instead of dealing with \( \hat{S}(t) \) directly, we will look at its log:

\[
\log[\hat{S}(t)] = \sum_{j: \tau_j < t} \log(1 - \hat{\lambda}_j)
\]

Thus, by approximate independence of the \( \hat{\lambda}_j \)'s,

\[
\text{var}(\log[\hat{S}(t)]) = \sum_{j: \tau_j < t} \text{var}[\log(1 - \hat{\lambda}_j)]
\]

by (A)

\[
= \sum_{j: \tau_j < t} \left( \frac{1}{1 - \hat{\lambda}_j} \right)^2 \text{var}(\hat{\lambda}_j)
\]

\[
= \sum_{j: \tau_j < t} \left( \frac{1}{1 - \hat{\lambda}_j} \right)^2 \hat{\lambda}_j(1 - \hat{\lambda}_j)/r_j
\]

\[
= \sum_{j: \tau_j < t} \frac{\hat{\lambda}_j}{(1 - \hat{\lambda}_j)r_j}
\]

\[
= \sum_{j: \tau_j < t} \frac{d_j}{(r_j - d_j)r_j}
\]

Now, \( \hat{S}(t) = \exp[\log[\hat{S}(t)]] \). Thus by (B),

\[
\text{var}(\hat{S}(t)) = [\hat{S}(t)]^2 \text{var}[\log[\hat{S}(t)]]
\]

**Greenwood’s Formula:**

\[
\text{var}(\hat{S}(t)) = [\hat{S}(t)]^2 \sum_{j: \tau_j < t} \frac{d_j}{(r_j - d_j)r_j}
\]
Back to confidence intervals

For a 95% confidence interval, we could use

\[ \hat{S}(t) \pm z_{1-\alpha/2} \text{se}[\hat{S}(t)] \]

where \( \text{se}[\hat{S}(t)] \) is calculated using Greenwood’s formula.

**Problem:** This approach can yield values > 1 or < 0.

**Better approach:** Get a 95% confidence interval for

\[ L(t) = \log(-\log(S(t))) \]

Since this quantity is unrestricted, the confidence interval will be in the proper range when we transform back.

**To see why this works, note the following:**

- Since \( \hat{S}(t) \) is an estimated probability
  \[ 0 \leq \hat{S}(t) \leq 1 \]
- Taking the log of \( \hat{S}(t) \) has bounds:
  \[ -\infty \leq \log[\hat{S}(t)] \leq 0 \]
- Taking the opposite:
  \[ 0 \leq -\log[\hat{S}(t)] \leq \infty \]
- Taking the log again:
  \[ -\infty \leq \log [-\log(\hat{S}(t))] \leq \infty \]

To transform back, reverse steps with \( S(t) = \exp(-\exp(L(t))) \)
Log-log Approach for Confidence Intervals:

(1) Define $L(t) = \log(-\log(S(t)))$

(2) Form a 95% confidence interval for $L(t)$ based on $\hat{L}(t)$, yielding $[\hat{L}(t) - A, \hat{L}(t) + A]$

(3) Since $S(t) = \exp(-\exp(L(t)))$, the confidence bounds for the 95% CI on $S(t)$ are:

$$[\exp(-e^{(\hat{L}(t) + A)}), \exp(-e^{(\hat{L}(t) - A)})]$$

(note that the upper and lower bounds switch)

(4) Substituting $\hat{L}(t) = \log(-\log(\hat{S}(t)))$ back into the above bounds, we get confidence bounds of

$$([\hat{S}(t)]e^A, [\hat{S}(t)]e^{-A})$$
What is A?

- $A$ is $1.96 \, \text{se}(\hat{L}(t))$
- To calculate this, we need to calculate
  \[
  \text{var}(\hat{L}(t)) = \text{var} \left[ \log(-\log(\hat{S}(t))) \right]
  \]
- From our previous calculations, we know
  \[
  \text{var}(\log[\hat{S}(t)]) = \sum_{j: \tau_j < t} \frac{d_j}{(r_j - d_j)r_j}
  \]
- Applying the delta method as in example (A), we get:
  \[
  \text{var}(\hat{L}(t)) = \text{var}(\log(-\log[\hat{S}(t)]))
  = \frac{1}{[\log \hat{S}(t)]^2} \sum_{j: \tau_j < t} \frac{d_j}{(r_j - d_j)r_j}
  \]
- We take the square root of the above to get $\text{se}(\hat{L}(t))$, and then form the confidence intervals as:
  \[
  \hat{S}(t)e^{\pm 1.96 \, \text{se}(\hat{L}(t))}
  \]
- This is the approach that Stata uses. Splus gives an option to calculate these bounds (use `conf.type='log-log'` in `surv.fit`).
Summary of Confidence Intervals on $S(t)$

- Calculate $\hat{S}(t) \pm 1.96 \text{se}[\hat{S}(t)]$ where $\text{se}[\hat{S}(t)]$ is calculated using Greenwood’s formula, and replace negative lower bounds by 0 and upper bounds greater than 1 by 1.
  - Recommended by Collett
  - This is the default using SAS
  - Not very satisfactory

- Use a log transformation to stabilize the variance and allow for non-symmetric confidence intervals. This is what is normally done for the confidence interval of an estimated odds ratio.
  - Use $\text{var}[\log(\hat{S}(t))] = \sum_{j: r_j < t} \frac{d_j}{(r_j - d_j)r_j}$ already calculated as part of Greenwood’s formula
  - This is the default in Splus

- Use the log-log transformation just described
  - Somewhat complicated, but always yields proper bounds
  - This is the default in Stata.
Software for Kaplan-Meier Curves

- Stata - stset and sts commands
- SAS - PROC LIFETEST
- Splus - surv.fit(time,status)

Defaults for Confidence Interval Calculations

- Stata - “log-log” \( \Rightarrow \hat{L}(t) \pm 1.96 \text{ se}[\hat{L}(t)] \)
  where \( L(t) = \log[- \log(S(t))] \)

- SAS - “plain” \( \Rightarrow \hat{S}(t) \pm 1.96 \text{ se}[\hat{S}(t)] \)

- Splus - “log” \( \Rightarrow \log S(t) \pm 1.96 \text{ se}[\log(\hat{S}(t))] \)

but Splus will also give either of the other two options if you request them.
Stata Commands

Create a file called “leukemia.dat” with the raw data, with a column for treatment, weeks to relapse (i.e., duration of remission), and relapse status:

```
.infile trt remiss status using leukemia.dat
.stset remiss status
.sts list
.sts graph, saving(kmtrt)
```

(sets up a failure time dataset, with failtime status in that order, type help stset to get details)

(estimated S(t), se[S(t)], and 95% CI)

(creates a Kaplan-Meier plot, and saves the plot in file kmtrt.gph, type ‘‘help gphdot’’ to get some printing instructions)

(redisplays the graph at any later time)

If the dataset has already been created and loaded into Stata, then you can substitute the following commands for initializing the data:

```
.use leukem
.describe
.stset remiss status
.stdes
```

(finds Stata dataset leukem.dta)

(provides a description of the dataset)

(declares data to be failure type)

(gives a description of the survival dataset)
**STATA Output for Treated Leukemia Patients:**

```stata
.use leukemia
.stset remiss status if trt==1
.sts list
```

```
failure time:  remiss
failure/censor: status

SAS Commands for Kaplan Meier Estimator - PROC LIFETEST

The SAS command for the Kaplan-Meier estimate is:

```sas
time failtime*censor(1);
or
time failtime*failind(0);
```

The first variable is the failure time, and the second is the failure or censoring indicator. In parentheses you need to put the specific numeric value that corresponds to censoring.

The upper and lower confidence limits on $\hat{S}(t)$ are included in the data set “OUTSURV” when specified. The upper and lower limits are called: `sdf_ucl, sdf_lcl`.

```sas
data leukemia;
  input weeks remiss;
  label weeks='Time to Remission (in weeks)'
    remiss='Remission indicator (1=yes,0=no)';
cards;
  6 1
  6 1
  ............ (lines edited out here)
  34 0
  35 0
;
proc lifetest data=leukemia outsurv=confint;
  time weeks*remiss(0);
  title 'Leukemia data from Table 1.1 of Cox and Oakes';
run;

proc print data=confint;
title '95% Confidence Intervals for Estimated Survival';
```

Output from SAS **PROC LIFETEST**

Note: this information is not printed if you use NOPRINT.

Leukemia data from Table 1.1 of Cox and Oakes

<td>1</td>
<td>.</td>
<td>.</td>
<td>.</td>
</tr>
</tbody>
</table>

The output dataset will have one observation for each unique combination of `WEEKS` and `_CENSOR_`. It will also add an observation for failure time equal to 0.
**Splus Commands**

Create a file called “leukemia.dat” with the variables names in the first row, as follows:

```
t   c
 6   1
 6   1
etc ...
```

In Splus, type

```r
y_read.table('leukemia.dat',header=T)
surv.fit(y$t,y$c)
plot(surv.fit(y$t,y$c))
```

(the plot command will also yield 95% confidence intervals)

To specify the type of confidence intervals, use the `conf.type=` option in the `surv.fit` statements: e.g. `conf.type="log-log"` or `conf.type="plain"`
```r
> surv.fit(y$t,y$c)
95 percent confidence interval is of type "log"

<table>

```
KM Survival Estimate and Confidence intervals (SPlus)
Means, Medians, Quantiles based on the KM

- **Mean**: $\sum_{j=1}^{k} \tau_j \Pr(T = \tau_j)$

- **Median** - by definition, this is the time, $\tau$, such that $S(\tau) = 0.5$. However, in practice, it is defined as the smallest time such that $\hat{S}(\tau) \leq 0.5$. The median is more appropriate for censored survival data than the mean.

For the treated leukemia patients, we find:

\[
\hat{S}(22) = 0.5378 \\
\hat{S}(23) = 0.4482
\]

The median is thus 23. This can also be seen visually on the graph to the left.

- **Lower quartile (25th percentile)**:
  the smallest time ($LQ$) such that $\hat{S}(LQ) \leq 0.75$

- **Upper quartile (75th percentile)**:
  the smallest time ($UQ$) such that $\hat{S}(UQ) \leq 0.25$
The (2) Lifetable Estimator of Survival:

We said that we would consider the following three methods for estimating a survivorship function

\[ S(t) = Pr(T \geq t) \]

without resorting to parametric methods:

(1) √ Kaplan-Meier

(2) ⇒ Life-table (Actuarial Estimator)

(3) ⇒ Cumulative hazard estimator
(2) The Lifetable or Actuarial Estimator

- one of the oldest techniques around
- used by actuaries, demographers, etc.
- applies when the data are grouped

Our goal is still to estimate the survival function, hazard, and density function, but this is complicated by the fact that we don’t know exactly when during each time interval an event occurs.
Lee (section 4.2) provides a good description of lifetable methods, and distinguishes several types according to the data sources:

**Population Life Tables**

- **cohort life table** - describes the mortality experience from birth to death for a particular cohort of people born at about the same time. People at risk at the start of the interval are those who survived the previous interval.

- **current life table** - constructed from (1) census information on the number of individuals alive at each age, for a given year and (2) vital statistics on the number of deaths or failures in a given year, by age. This type of lifetable is often reported in terms of a hypothetical cohort of 100,000 people.

Generally, censoring is not an issue for Population Life Tables.

**Clinical Life tables** - applies to grouped survival data from studies in patients with specific diseases. Because patients can enter the study at different times, or be lost to follow-up, censoring must be allowed.
Notation

- the $j$-th time interval is $[t_{j-1}, t_j)$
- $c_j$ - the number of censorings in the $j$-th interval
- $d_j$ - the number of failures in the $j$-th interval
- $r_j$ is the number entering the interval

Example: 2418 Males with Angina Pectoris (Lee, p.91)

<table>
<thead>
<tr>
<th>Year after Diagnosis</th>
<th>$j$</th>
<th>$d_j$</th>
<th>$c_j$</th>
<th>$r_j$</th>
<th>$r'_j = r_j - c_j/2$</th>
</tr>
</thead>

</tbody>
</table>
Estimating the survivorship function

We could apply the K-M formula directly to the numbers in the table on the previous page, estimating $S(t)$ as

$$
\hat{S}(t) = \prod_{j: \tau_j < t} \left(1 - \frac{d_j}{r_j}\right)
$$

However, this approach is unsatisfactory for grouped data.... it treats the problem as though it were in discrete time, with events happening only at 1 yr, 2 yr, etc. In fact, what we are trying to calculate here is the conditional probability of dying within the interval, given survival to the beginning of it.

What should we do with the censored people?

We can assume that censorings occur:

- at the beginning of each interval: $r'_j = r_j - c_j$
- at the end of each interval: $r'_j = r_j$
- on average halfway through the interval:
  $$r'_j = r_j - c_j/2$$

The last assumption yields the Actuarial Estimator. It is appropriate if censorings occur uniformly throughout the interval.
Constructing the lifetable

First, some additional notation for the $j$-th interval, $[t_{j-1}, t_j)$:

- **Midpoint** ($t_{mj}$) - useful for plotting the density and the hazard function
- **Width** ($b_j = t_j - t_{j-1}$) needed for calculating the hazard in the $j$-th interval

**Quantities estimated:**

- Conditional probability of dying
  \[
  \hat{q}_j = \frac{d_j}{r'_j}
  \]
- Conditional probability of surviving
  \[
  \hat{p}_j = 1 - \hat{q}_j
  \]
- Cumulative probability of surviving at $t_j$:
  \[
  \hat{S}(t_j) = \prod_{\ell \leq j} \hat{p}_\ell \\
  = \prod_{\ell \leq j} \left(1 - \frac{d_\ell}{r'_{\ell'}}\right)
  \]
Some important points to note:

- Because the intervals are defined as \([t_{j-1}, t_j]\), the first interval typically starts with \(t_0 = 0\).

- Stata estimates the survival function at the right-hand endpoint of each interval, i.e., \(S(t_j)\)

- However, SAS estimates the survival function at the left-hand endpoint, \(S(t_{j-1})\).

- The implication in SAS is that \(\hat{S}(t_0) = 1\) and \(\hat{S}(t_1) = p_1\)
Other quantities estimated at the midpoint of the $j$-th interval:

- **Hazard** in the $j$-th interval:
  \[
  \hat{\lambda}(t_{m_j}) = \frac{d_j}{b_j(r'_j - d_j/2)}
  \]
  \[
  = \frac{\hat{q}_j}{b_j(1 - \hat{q}_j/2)}
  \]
  the number of deaths in the interval divided by the average number of survivors at the midpoint

- **density** at the midpoint of the $j$-th interval:
  \[
  \hat{f}(t_{m_j}) = \frac{\hat{S}(t_{j-1}) - \hat{S}(t_j)}{b_j}
  \]
  \[
  = \frac{\hat{S}(t_{j-1}) \hat{q}_j}{b_j}
  \]

Note: Another way to get this is:

\[
\hat{f}(t_{m_j}) = \hat{\lambda}(t_{m_j}) \hat{S}(t_{m_j})
\]
\[
= \hat{\lambda}(t_{m_j})[\hat{S}(t_j) + \hat{S}(t_{j-1})]/2
\]
Constructing the Lifetable using Stata

Uses the `ltable` command.

If the raw data are already grouped, then the `freq` statement must be used when reading the data.

```stata
. infile years status count using angina.dat
(32 observations read)

. ltable years status [freq=count]
```

<table>

</table>

There is also a "failure" option which gives the number of failures (like the default), and also provides a 95% confidence interval on the cumulative failure probability.
Constructing the lifetable using SAS

If the raw data are already grouped, then the FREQ statement must be used when reading the data.

SAS requires that the interval endpoints be specified, using one of the following (see SAS manual or online help for more detail):

- **intervals** - specify the interval endpoints
- **width** - specify the width of each interval
- **ninterval** - specify the number of intervals

Suppose we wish to use the actuarial method, but the data do not come grouped.

Consider the treated nursing home patients, with length of stay (los) grouped into 100 day intervals:

```
.use nurshome
.drop if rx==0               (keep only the treated patients)
(881 observations deleted)
.stset los fail
.1table los fail, intervals(100)
```

Examples for Nursing home data:

Estimated Survival:

Duration of stay in nursing homes

Estimated Survival

Lower Limit of Time Interval

0 100 200 300 400 500 600 700 800 900 1000
Estimated hazard:

Duration of stay in nursing homes

Estimated hazard
(3) Estimating the cumulative hazard
(Nelson-Aalen estimator)

Suppose we want to estimate $\Lambda(t) = \int_0^t \lambda(u)du$, the cumulative hazard at time $t$.

Just as we did for the KM, think of dividing the observed timespan of the study into a series of fine intervals so that there is only one event per interval:

| | | D | | C | | C | D | D | D |

$\Lambda(t)$ can then be approximated by a sum:

$$\hat{\Lambda}(t) = \sum_j \lambda_j \Delta$$

where the sum is over intervals, $\lambda_j$ is the value of the hazard in the $j$-th interval and $\Delta$ is the width of each interval. Since $\hat{\lambda} \Delta$ is approximately the probability of dying in the interval, we can further approximate by

$$\hat{\Lambda}(t) = \sum_j d_j / r_j$$

It follows that $\Lambda(t)$ will change only at death times, and hence we write the Nelson-Aalen estimator as:

$$\hat{\Lambda}_{NA}(t) = \sum_{j: \tau_j < t} d_j / r_j$$
<table>
<thead>
<tr>
<th>( r_j )</th>
<th>n</th>
<th>n</th>
<th>n</th>
<th>n-1</th>
<th>n-2</th>
<th>n-3</th>
<th>n-4</th>
</tr>
</thead>
<tbody>
<tr>
<td>( d_j )</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>( c_j )</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>( \hat{\lambda}(t_j) )</td>
<td>0</td>
<td>0</td>
<td>1/n</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1/n-3</td>
</tr>
<tr>
<td>( \hat{\Lambda}(t_j) )</td>
<td>0</td>
<td>0</td>
<td>1/n</td>
<td>1/n</td>
<td>1/n</td>
<td>1/n</td>
<td>1/n</td>
</tr>
</tbody>
</table>

Once we have \( \hat{\Lambda}_{NA}(t) \), we can also find another estimator of \( S(t) \) (Fleming-Harrington):

\[
\hat{S}_{FH}(t) = \exp(-\hat{\Lambda}_{NA}(t))
\]

In general, this estimator of the survival function will be close to the Kaplan-Meier estimator, \( \hat{S}_{KM}(t) \)

We can also go the other way ... we can take the Kaplan-Meier estimate of \( S(t) \), and use it to calculate an alternative estimate of the cumulative hazard function:

\[
\hat{\Lambda}_{KM}(t) = -\log \hat{S}_{KM}(t)
\]
Stata commands for FH Survival Estimate

Say we want to obtain the Fleming-Harrington estimate of the survival function for married females, in the healthiest initial subgroup, who are randomized to the untreated group of the nursing home study.

First, we use the following commands to calculate the Nelson-Aalen cumulative hazard estimator:

```
use nurshome
keep if rx==0 & gender==0 & health==2 & married==1
sts list, na
```

```
failure _d: fail
analysis time _t: los
```

99
After generating the Nelson-Aalen estimator, we manually have to create a variable for the survival estimate:

```
. sts gen nelson=na

gensfh=exp(-nelson)

. list sfh
```

```
sfh
 1.  .9200444
 2.  .8400932
 3.  .7601478
 4.  .6802101
 5.  .6002833
 6.  .5203723
 7.  .4404857
 8.  .3606392
 9.  .2808661
10.  .2012493
11.  .1220639
12.  .0449048
```

Additional built-in functions can be used to generate 95% confidence intervals on the FH survival estimate.
We can compare the Fleming-Harrington survival estimate to the KM estimate by rerunning the `sts list` command:

```
. sts list

. sts gen skm=s

. list skm sfh

<table>
<thead>
<tr>
<th>skm</th>
<th>sfh</th>
</tr>
</thead>
<tbody>
<tr>
<td>.91666667</td>
<td>.9200444</td>
</tr>
<tr>
<td>.83333333</td>
<td>.8400932</td>
</tr>
<tr>
<td>.75</td>
<td>.7601478</td>
</tr>
<tr>
<td>.66666667</td>
<td>.6802101</td>
</tr>
<tr>
<td>.58333333</td>
<td>.6002833</td>
</tr>
<tr>
<td>.5</td>
<td>.5203723</td>
</tr>
<tr>
<td>.41666667</td>
<td>.4404857</td>
</tr>
<tr>
<td>.33333333</td>
<td>.3606392</td>
</tr>
<tr>
<td>.25</td>
<td>.2808661</td>
</tr>
<tr>
<td>.16666667</td>
<td>.2012493</td>
</tr>
<tr>
<td>.08333333</td>
<td>.1220639</td>
</tr>
<tr>
<td>0</td>
<td>.0449048</td>
</tr>
</tbody>
</table>
```

In this example, it looks like the Fleming-Harrington estimator is slightly higher than the KM at every time point, but with larger datasets the two will typically be much closer.

Comparison of Survival Curves

We spent the last class looking at some nonparametric approaches for estimating the survival function, \( \hat{S}(t) \), over time for a single sample of individuals.

Now we want to compare the survival estimates between two groups.

Example: Time to remission of leukemia patients

**Comparison of Treatments Using Kaplan–Meier Survival Estimates**

<table>
<thead>
<tr>
<th>Treatment</th>

<td>21</td>
<td>8.0</td>
</tr>
</tbody>
</table>

![Graph showing comparison of survival curves for two treatments.](image-url)
How can we form a basis for comparison?

At a specific point in time, we could see whether the confidence intervals for the survival curves overlap.

However, the confidence intervals we have been calculating are "pointwise" \( \Rightarrow \) they correspond to a confidence interval for \( \hat{S}(t^*) \) at a single point in time, \( t^* \).

In other words, we can’t say that the true survival function \( S(t) \) is contained between the pointwise confidence intervals with 95% probability.

(Aside: if you’re interested, the issue of confidence bands for the estimated survival function are discussed in Section 4.4 of Klein and Moeschberger)
Looking at whether the confidence intervals for $\hat{S}(t^*)$ overlap between the 6MP and placebo groups would only focus on comparing the two treatment groups at a single point in time, $t^*$. We want an overall comparison.

**Should we base our overall comparison of $\hat{S}(t)$ on:**

- the farthest distance between the two curves?
- the median survival for each group?
- the average hazard? (for exponential distributions, this would be like comparing the mean event times)
- adding up the difference between the two survival estimates over time?
  $$\sum_j [\hat{S}(t_{jA}) - \hat{S}(t_{jB})]$$
- a weighted sum of differences, where the weights reflect the number at risk at each time?
- a rank-based test? i.e., we could rank all of the event times, and then see whether the sum of ranks for one group was less than the other.
Nonparametric comparisons of groups

All of these are pretty reasonable options, and we’ll see that there have been several proposals for how to compare the survival of two groups. For the moment, we are sticking to nonparametric comparisons.

Why nonparametric?

- fairly robust
- efficient relative to parametric tests
- often simple and intuitive

Before continuing the description of the two-sample comparison, I’m going to try to put this in a general framework to give a perspective of where we’re heading in this class.
General Framework for Survival Analysis

We observe \((X_i, \delta_i, Z_i)\) for individual \(i\), where

- \(X_i\) is a censored failure time random variable
- \(\delta_i\) is the failure/censoring indicator
- \(Z_i\) represents a set of covariates

Note that \(Z_i\) might be a scalar (a single covariate, say treatment or gender) or may be a \((p \times 1)\) vector (representing several different covariates).

These covariates might be:

- continuous
- discrete
- time-varying (more later)

If \(Z_i\) is a scalar and is binary, then we are comparing the survival of two groups, like in the leukemia example.

More generally though, it is useful to build a model that characterizes the relationship between survival and all of the covariates of interest.
We’ll proceed as follows:

- Two group comparisons
- Multigroup and stratified comparisons - stratified logrank
- Failure time regression models
  - Cox proportional hazards model
  - Accelerated failure time model
Two sample tests

- Mantel-Haenszel logrank test
- Peto & Peto’s version of the logrank test
- Gehan’s Generalized Wilcoxon
- Peto & Peto’s and Prentice’s generalized Wilcoxon
- Tarone-Ware and Fleming-Harrington classes
- Cox’s F-test (non-parametric version)

Mantel-Haenszel Logrank test

The logrank test is the most well known and widely used.

It also has an intuitive appeal, building on standard methods for binary data. (Later we will see that it can also be obtained as the score test from a partial likelihood from the Cox Proportional Hazards model.)

First consider the following \((2 \times 2)\) table classifying those with and without the event of interest in a two group setting:

<table>
<thead>
<tr>
<th>Group</th>
<th>Event</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Yes</td>
<td>No</td>
</tr>
<tr>
<td>0</td>
<td>(d_0)</td>
<td>(n_0 - d_0)</td>
</tr>
<tr>
<td>1</td>
<td>(d_1)</td>
<td>(n_1 - d_1)</td>
</tr>
<tr>
<td>Total</td>
<td>(d)</td>
<td>(n - d)</td>
</tr>
</tbody>
</table>
If the margins of this table are considered fixed, then $d_0$ follows a \__\__\__\__\__\__ distribution. Under the null hypothesis of no association between the event and group, it follows that

\[
E(d_0) = \frac{n_0 d}{n}
\]

\[
Var(d_0) = \frac{n_0 n_1 d(n - d)}{n^2(n - 1)}
\]

Therefore, under $H_0$:

\[
\chi^2_{MH} = \frac{[d_0 - n_0 d/n]^2}{\frac{n_0 n_1 d(n - d)}{n^2(n - 1)}} \sim \chi_1^2
\]

This is the Mantel-Haenszel statistic and is approximately equivalent to the Pearson $\chi^2$ test for equality of the two groups given by:

\[
\chi^p_2 = \sum \frac{(o - e)^2}{e}
\]

Note: recall that the Pearson $\chi^2$ test was derived for the case where only the row margins were fixed, and thus the variance above was replaced by:

\[
Var\left(d_0 - \frac{n_0(d_0 + d_1)}{n}\right) = \frac{n_0 n_1 d(n - d)}{n^3}
\]
Example: Toxicity in a clinical trial with two treatments

<table>
<thead>
<tr>
<th>Group</th>
<th>Yes</th>
<th>No</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>8</td>
<td>42</td>
<td>50</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>48</td>
<td>50</td>
</tr>
<tr>
<td>Total</td>
<td>10</td>
<td>90</td>
<td>100</td>
</tr>
</tbody>
</table>

\[ \chi_p^2 = 4.00 \quad (p = 0.046) \]

\[ \chi_{MH}^2 = 3.96 \quad (p = 0.047) \]
Now suppose we have $K$ ($2 \times 2$) tables, all independent, and we want to test for a common group effect. The Cochran-Mantel-Haenszel test for a common odds ratio not equal to 1 can be written as:

$$
\chi^2_{CMH} = \frac{\left[\sum^K_{j=1}(d_{0j} - n_{0j} \times d_j/n_j)\right]^2}{\sum^K_{j=1} n_{1j}n_{0j}d_j(n_j - d_j)/[n_j^2(n_j - 1)]}
$$

where the subscript $j$ refers to the $j$-th table:

<table>
<thead>
<tr>
<th>Group</th>
<th>Event</th>
<th>Yes</th>
<th>No</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td></td>
<td>$d_{0j}$</td>
<td>$n_{0j} - d_{0j}$</td>
<td>$n_{0j}$</td>
</tr>
<tr>
<td>1</td>
<td></td>
<td>$d_{1j}$</td>
<td>$n_{1j} - d_{1j}$</td>
<td>$n_{1j}$</td>
</tr>
<tr>
<td>Total</td>
<td></td>
<td>$d_j$</td>
<td>$n_j - d_j$</td>
<td>$n_j$</td>
</tr>
</tbody>
</table>

This statistic is distributed approximately as $\chi^2_1$. 
How does this apply in survival analysis?

Suppose we observe

**Group 1**: \((X_{11}, \delta_{11}) \ldots (X_{1n_1}, \delta_{1n_1})\)

**Group 0**: \((X_{01}, \delta_{01}) \ldots (X_{0n_0}, \delta_{0n_0})\)

We could just count the numbers of failures: \(d_1 = \sum_{j=1}^{K} \delta_{1j}\)

**Example: Leukemia data**, just counting up the number of remissions in each treatment group.

<table>
<thead>
<tr>
<th>Group</th>
<th>Yes</th>
<th>No</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>21</td>
<td>0</td>
<td>21</td>
</tr>
<tr>
<td>1</td>
<td>9</td>
<td>12</td>
<td>21</td>
</tr>
<tr>
<td>Total</td>
<td>30</td>
<td>12</td>
<td>42</td>
</tr>
</tbody>
</table>

\[
\chi^2_p = 16.8 \quad (p = 0.001)
\]

\[
\chi^2_{MH} = 16.4 \quad (p = 0.001)
\]

But, this doesn’t account for the time at risk.

Conceptually, we would like to compare the KM survival curves. Let’s put the components side-by-side and compare.

<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1</td>
<td>5</td>
</tr>
</tbody>
</table>

Note that I wrote down the number at risk for Group 1 for times 1-5 even though there were no events or censorings at those times.
Logrank Test: Formal Definition

The logrank test is obtained by constructing a \((2 \times 2)\) table at each distinct death time, and comparing the death rates between the two groups, conditional on the number at risk in the groups. The tables are then combined using the Cochran-Mantel-Haenszel test.

Note: The logrank is sometimes called the Cox-Mantel test.

Let \(t_1, ..., t_K\) represent the \(K\) ordered, distinct death times. At the \(j\)-th death time, we have the following table:

<table>
<thead>
<tr>
<th>Group</th>
<th>Die/Fail</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Yes</td>
</tr>
<tr>
<td>0</td>
<td>(d_{0j})</td>
</tr>
<tr>
<td>1</td>
<td>(d_{1j})</td>
</tr>
<tr>
<td>Total</td>
<td>(d_j)</td>
</tr>
</tbody>
</table>

where \(d_{0j}\) and \(d_{1j}\) are the number of deaths in group 0 and 1, respectively at the \(j\)-th death time, and \(r_{0j}\) and \(r_{1j}\) are the number at risk at that time, in groups 0 and 1.
The logrank test is:

\[ \chi^2_{\text{logrank}} = \frac{\sum_{j=1}^{K} (d_{0j} - r_{0j} \star d_j / r_j)^2}{\sum_{j=1}^{K} \frac{r_{1j} r_{0j} d_j (r_j - d_j)}{r_j^2 (r_j - 1)}} \]

Assuming the tables are all independent, then this statistic will have an approximate \( \chi^2 \) distribution with 1 df.

Based on the motivation for the logrank test, which of the survival-related quantities are we comparing at each time point?

- \( \sum_{j=1}^{K} w_j \left[ \hat{S}_1(t_j) - \hat{S}_2(t_j) \right] \)  
- \( \sum_{j=1}^{K} w_j \left[ \hat{\lambda}_1(t_j) - \hat{\lambda}_2(t_j) \right] \)  
- \( \sum_{j=1}^{K} w_j \left[ \hat{\Lambda}_1(t_j) - \hat{\Lambda}_2(t_j) \right] \)

Note: Although CMH works to get the correct logrank test, it would require inputting the $d_j$ and $r_j$ at each time of death for each treatment group. There’s an easier way to get the test statistic, which I’ll show you shortly.
Calculating logrank statistic by hand

<td><strong>6.257</strong></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

$o_j = d_{0j}$
$e_j = d_j r_{0j} / r_j$
$v_j = r_{1j} r_{0j} d_j (r_j - d_j) / [r_j^2 (r_j - 1)]$

$\chi^2_{\text{logrank}} = \frac{(10.251)^2}{6.257} = 16.793$
Notes about logrank test:

- The logrank statistic depends on ranks of event times only.

- If there are no tied deaths, then the logrank has the form:
  \[
  \frac{\left[\sum_{j=1}^{K} (d_{0j} - \frac{r_{0j}}{r_j})\right]^2}{\sum_{j=1}^{K} r_{1j}r_{0j}/r_j^2}
  \]

- Numerator can be interpreted as \(\Sigma (o - e)\) where “o” is the observed number of deaths in group 0, and “e” is the expected number, given the risk set. The expected number equals \#deaths \times proportion in group 0 at risk.

- The \((o - e)\) terms in the numerator can be written as
  \[
  \frac{r_{0j}r_{1j}}{r_j} (\hat{\lambda}_{1j} - \hat{\lambda}_{0j})
  \]

- It does not matter which group you choose to sum over.

  To see this, note that if we summed up \((o-e)\) over the death times for the 6MP group we would get -10.251, and the sum of the variances is the same. So when we square the numerator, the test statistic is the same.
Analogous to the CMH test for a series of tables at different levels of a confounder, the logrank test is most powerful when “odds ratios” are constant over time intervals. That is, it is most powerful for \textit{proportional hazards}.

\textbf{Checking the assumption of proportional hazards:}

- check to see if the estimated survival curves cross - if they do, then this is evidence that the hazards are \textit{not} proportional

- more formal test: \textit{any ideas?}

\textbf{What should be done if the hazards are \textit{not} proportional?}

- If the difference between hazards has a consistent sign, the logrank test usually does well.

- Other tests are available that are more powerful against different alternatives.
Getting the logrank statistic using Stata:

After declaring data as survival type data using the “stset” command, issue the “sts test” command

```
. stset remiss status
    data set name: leukem
    id: -- (meaning each record a unique subject)
    entry time: -- (meaning all entered at time 0)
    exit time: remiss
    failure/censor: status

. sts list, by(trt)

<table>

Pr>chi2 = 0.0000
```
Getting the logrank statistic using SAS

- Still use PROC LIFETEST
- Add “STRATA” command, with treatment variable
- Gives the chi-square test (2-sided), but also gives you the terms you need to calculate the 1-sided test; this is useful if we want to know which of the two groups has the higher estimated hazard over time.
- The STRATA command also gives the Gehan-Wilcoxon test (which we will talk about next)

```
Title 'Cox and Oakes example';
data leukemia;
   input weeks remiss trtmt;
cards;
   6   0   1
   6   1   1
   6   1   1
   6   1   1 /* data for 6MP group */
   7   1   1
   9   0   1

Getting the logrank statistic using Splus:

Instead of the “surv.fit” command, use the “surv.diff” command with a “group” (treatment) variable.

Mantel-Haenszel logrank:

```r
> logrank<-surv.diff(weeks,remiss,trtmt)
> logrank

   N Observed Expected (O-E)^2/E
0 21 21 10.75 9.775
1 21  9 19.25 5.458

Chisq= 16.8 on 1 degrees of freedom, p= 4.169e-05
```
Generalization of logrank test

Linear rank tests

The logrank and other tests can be derived by assigning scores to the ranks of the death times, and are members of a general class of linear rank tests (for more detail, see Lee, ch 5)

First, define

\[ \hat{\Lambda}(t) = \sum_{j : t_j < t} \frac{d_j}{r_j} \]

where \( d_j \) and \( r_j \) are the number of deaths and the number at risk, respectively at the \( j \)-th ordered death time.

Then assign these scores (suggested by Peto and Peto):

<table>
<thead>
<tr>
<th>Event</th>
<th>Score</th>
</tr>
</thead>
<tbody>
<tr>
<td>Death at ( t_j )</td>
<td>( w_j = 1 - \hat{\Lambda}(t_j) )</td>
</tr>
<tr>
<td>Censoring at ( t_j )</td>
<td>( w_j = -\hat{\Lambda}(t_j) )</td>
</tr>
</tbody>
</table>

To calculate the logrank test, simply sum up the scores for group 0.
Example

Group 0: 15, 18, 19, 19, 20

Group 1: 16+, 18+, 20+, 23, 24+

Calculation of logrank as a linear rank statistic

<table>
<thead>
<tr>
<th>Ordered Data</th>
<th>Group</th>
<th>$d_j$</th>
<th>$r_j$</th>
<th>$\Lambda(t_j)$</th>
<th>score $w_j$</th>
</tr>
</thead>
<tbody>
<tr>
<td>15</td>
<td>0</td>
<td>1</td>
<td>10</td>
<td>0.100</td>
<td>0.900</td>
</tr>
<tr>
<td>16+</td>
<td>1</td>
<td>0</td>
<td>9</td>
<td>0.100</td>
<td>-0.100</td>
</tr>
<tr>
<td>18</td>
<td>0</td>
<td>1</td>
<td>8</td>
<td>0.225</td>
<td>0.775</td>
</tr>
<tr>
<td>18+</td>
<td>1</td>
<td>0</td>
<td>7</td>
<td>0.225</td>
<td>-0.225</td>
</tr>
<tr>
<td>19</td>
<td>0</td>
<td>2</td>
<td>6</td>
<td>0.558</td>
<td>0.442</td>
</tr>
<tr>
<td>20</td>
<td>0</td>
<td>1</td>
<td>4</td>
<td>0.808</td>
<td>0.192</td>
</tr>
<tr>
<td>20+</td>
<td>1</td>
<td>0</td>
<td>3</td>
<td>0.808</td>
<td>-0.808</td>
</tr>
<tr>
<td>23</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>1.308</td>
<td>-0.308</td>
</tr>
<tr>
<td>24+</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>1.308</td>
<td>-1.308</td>
</tr>
</tbody>
</table>

The logrank statistic $S$ is sum of scores for group 0:

$$S = 0.900 + 0.775 + 0.442 + 0.442 + 0.192 = 2.75$$

The variance is:

$$Var(S) = \frac{n_0 n_1 \sum_{j=1}^{n} w_j^2}{n(n-1)}$$

In this case, $Var(S) = 1.210$, so

$$Z = \frac{2.75}{\sqrt{1.210}} = 2.50 \implies \chi^2_{\text{logrank}} = (2.50)^2 = 6.25$$
Why is this form of the logrank equivalent?

The logrank statistic $S$ is equivalent to $\Sigma (o - e)$ over the distinct death times, where “$o$” is the observed number of deaths in group 0, and “$e$” is the expected number, given the risk sets.

At deaths: weights are $1 - \hat{\Lambda}$  
At censorings: weights are $-\hat{\Lambda}$

So we are summing up “1’s” for deaths (to get $d_{0j}$), and subtracting $-\hat{\Lambda}$ at both deaths and censorings. This amounts to subtracting $d_j/r_j$ at each death or censoring time in group 0, at or after the $j$-th death. Since there are a total of $r_{0j}$ of these, we get $e = r_{0j} * d_j/r_j$.

Why is it called the logrank test?

Since $S(t) = \exp(-\Lambda(t))$, an alternative estimator of $S(t)$ is:

$$\hat{S}(t) = \exp(-\hat{\Lambda(t)}) = \exp(-\sum_{j:t_j \leq t} \frac{d_j}{r_j})$$

So, we can think of $\hat{\Lambda(t)} = - \log(\hat{S}(t))$ as yielding the “log-survival” scores used to calculate the statistic.
Comparing the CMH-type Logrank and “Linear Rank” logrank

A. CMH-type Logrank:
We motivated the logrank test through the CMH statistic for testing $H_0: \text{OR} = 1$ over $K$ tables, where $K$ is the number of distinct death times. This turned out to be what we get when we use the logrank (default) option in Stata or the “STRATA” statement in SAS.

B. Linear Rank logrank:
The linear rank version of the logrank test is based on adding up “scores” for one of the two treatment groups. The particular scores that gave us the same logrank statistic were based on the Nelson-Aalen estimator, i.e., $\hat{A} = \sum \hat{\lambda}(t_j)$. This is what you get when you use the “TEST” statement in SAS.

Here are some comparisons, with a new example to show when the two types of logrank statistics will be equal.
First, let’s go back to our example from Chapter 5 of Lee:

**Example**  
Group 0: 15, 18, 19, 19, 20  
Group 1: 16+, 18+, 20+, 23, 24+

### A. The CMH-type logrank statistic:  
(using the STRATA statement)

#### Rank Statistics

<table>
<thead>
<tr>
<th>TRTMT</th>
<th>Log-Rank</th>
<th>Wilcoxon</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control</td>
<td>2.7500</td>
<td>18.000</td>
</tr>
<tr>
<td>Treated</td>
<td>-2.7500</td>
<td>-18.000</td>
</tr>
</tbody>
</table>

#### Covariance Matrix for the Log-Rank Statistics

<table>
<thead>
<tr>
<th>TRTMT</th>
<th>Control</th>
<th>Treated</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control</td>
<td>1.08750</td>
<td>-1.08750</td>
</tr>
<tr>
<td>Treated</td>
<td>-1.08750</td>
<td>1.08750</td>
</tr>
</tbody>
</table>

#### Test of Equality over Strata

<table>
<thead>
<tr>
<th>Test</th>
<th>Chi-Square</th>
<th>DF</th>
<th>Pr &gt; Chi-Square</th>
</tr>
</thead>
<tbody>
<tr>
<td>Log-Rank</td>
<td>6.9540</td>
<td>1</td>
<td>0.0084</td>
</tr>
<tr>
<td>Wilcoxon</td>
<td>5.5479</td>
<td>1</td>
<td>0.0185</td>
</tr>
<tr>
<td>-2Log(LR)</td>
<td>3.3444</td>
<td>1</td>
<td>0.0674</td>
</tr>
</tbody>
</table>
This is exactly the same chi-square test that you would get if you calculated the numerator of the logrank as $\Sigma(o_j - e_j)$ and the variance as $v_j = r_{1j}r_{0j}d_j(r_j - d_j)/[r_j^2(r_j - 1)]$

<table>
<thead>
<tr>
<th>Ordered Group 0 Combined</th>
<th>Group 0</th>
<th>Combined</th>
</tr>
</thead>
<tbody>
<tr>
<td>Death Times</td>
<td>$d_{0j}$</td>
<td>$r_{0j}$</td>
</tr>
<tr>
<td>15</td>
<td>1</td>
<td>5</td>

</tbody>
</table>

Sum(grp 0)   | 2.7500 |
Note that the numerator is the exact same number (2.75) in both versions of the logrank test. The difference in the denominator is due to the way that ties are handled.

**CMH-type variance:**

\[
var = \sum r_{1j}r_{0j}d_j(r_j - d_j) \\
= \sum \frac{r_{1j}r_{0j}d_j(r_j - d_j)}{r_j(r_j - 1)} \\
= \sum \frac{r_{1j}r_{0j}}{r_j(r_j - 1)} \frac{d_j(r_j - d_j)}{r_j}
\]

**Linear rank type variance:**

\[
var = \frac{n_0n_1\sum_{j=1}^n w_j^2}{n(n - 1)}
\]
Now consider an example where there are no tied death times

**Example I**

Group 0: 15, 18, 19, 21, 22
Group 1: 16+, 17+, 20+, 23, 24+

**A. The CMH-type logrank statistic:**
*(using the STRATA statement)*

**Rank Statistics**

<table>
<thead>
<tr>
<th>TRTMT</th>
<th>Log-Rank</th>
<th>Wilcoxon</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control</td>
<td>2.5952</td>
<td>15.000</td>
</tr>
<tr>
<td>Treated</td>
<td>-2.5952</td>

<thead>
<tr>
<th>TRTMT</th>
<th>Control</th>
<th>Treated</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control</td>
<td>1.21712</td>
<td>-1.21712</td>
</tr>
<tr>
<td>Treated</td>
<td>-1.21712</td>
<td>1.21712</td>
</tr>
</tbody>
</table>

**Test of Equality over Strata**

<table>
<thead>
<tr>
<th>Test</th>
<th>Chi-Square</th>
<th>DF</th>
<th>Pr &gt; Chi-Square</th>
</tr>
</thead>
<tbody>
<tr>
<td>Log-Rank</td>
<td>5.5338</td>
<td>1</td>
<td>0.0187</td>
</tr>
<tr>
<td>Wilcoxon</td>
<td>4.3269</td>
<td>1</td>
<td>0.0375</td>
</tr>
<tr>
<td>-2Log(LR)</td>
<td>3.1202</td>
<td>1</td>
<td>0.0773</td>
</tr>
</tbody>
</table>
B. The “linear rank” logrank statistic: (using the TEST statement)

Univariate Chi-Squares for the LOG RANK Test

<table>
<thead>
<tr>
<th>Variable</th>
<th>Test Statistic</th>
<th>Standard Deviation</th>
<th>Chi-Square</th>
<th>Pr &gt; Chi-Square</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRTMT</td>
<td>2.5952</td>
<td>1.1032</td>
<td>5.5338</td>
<td>0.0187</td>
</tr>
</tbody>
</table>

Covariance Matrix for the LOG RANK Statistics

<table>
<thead>
<tr>
<th>Variable</th>
<th>TRTMT</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRTMT</td>
<td>1.21712</td>
</tr>
</tbody>
</table>

Note that this time, the variances of the two logrank statistics are exactly the same, equal to 1.217.

If there are no tied event times, then the two versions of the test will yield identical results. The more ties we have, the more it matters which version we use.
Gehan’s Generalized Wilcoxon Test

First, let’s review the Wilcoxon test for uncensored data:

Denote observations from two samples by:

\((X_1, X_2, \ldots, X_n)\) and \((Y_1, Y_2, \ldots, Y_m)\)

Order the combined sample and define:

\[ Z_{(1)} < Z_{(2)} < \cdots < Z_{(m+n)} \]

\[ R_{i1} = \text{rank of } X_i \]

\[ R_1 = \sum_{i=1}^{m+n} R_{i1} \]

Reject \(H_0\) if \(R_1\) is too big or too small, according to

\[
\frac{R_1 - E(R_1)}{\sqrt{Var(R_1)}} \sim N(0, 1)
\]

where

\[ E(R_1) = \frac{m(m + n + 1)}{2} \]

\[ Var(R_1) = \frac{mn(m + n + 1)}{12} \]
The **Mann-Whitney** form of the Wilcoxon is defined as:

\[ U(X_i, Y_j) = U_{ij} = \begin{cases} +1 & \text{if } X_i > Y_j \\ 0 & \text{if } X_i = Y_j \\ -1 & \text{if } X_i < Y_j \end{cases} \]

and

\[ U = \sum_{i=1}^{n} \sum_{j=1}^{m} U_{ij}. \]

There is a simple correspondence between \( U \) and \( R_1 \):

\[ R_1 = m(m + n + 1)/2 + U/2 \]

so

\[ U = 2R_1 - m(m + n + 1) \]

Therefore,

\[ E(U) = 0 \]

\[ Var(U) = mn(m + n + 1)/3 \]
Extending Wilcoxon to censored data

The Mann-Whitney form leads to a generalization for censored data. Define

\[ U(X_i, Y_j) = U_{ij} = \begin{cases} 
+1 & \text{if } x_i > y_j \text{ or } x_i^+ \geq y_j \\
0 & \text{if } x_i = y_i \text{ or lower value censored} \\
-1 & \text{if } x_i < y_j \text{ or } x_i \leq y_j^+ 
\end{cases} \]

Then define

\[ W = \sum_{i=1}^{n} \sum_{j=1}^{m} U_{ij} \]

Thus, there is a contribution to \( W \) for every comparison where both observations are failures (except for ties), or where a censored observation is greater than or equal to a failure.

Looking at all possible pairs of individuals between the two treatment groups makes this a nightmare to compute by hand!
Gehan found an easier way to compute the above. First, pool the sample of \((n + m)\) observations into a single group, then compare each individual with the remaining \(n + m - 1\):

For comparing the \(i\)-th individual with the \(j\)-th, define

\[
U_{ij} = \begin{cases} 
+1 & \text{if } t_i > t_j \text{ or } t_i^+ \geq t_j \\
-1 & \text{if } t_i < t_j \text{ or } t_i \leq t_j^+ \\
0 & \text{otherwise}
\end{cases}
\]

Then

\[
U_i = \sum_{j=1}^{m+n} U_{ij}
\]

Thus, for the \(i\)-th individual, \(U_i\) is the number of observations which are definitely less than \(t_i\) minus the number of observations that are definitely greater than \(t_i\). We assume censorings occur after deaths, so that if \(t_i = 18^+\) and \(t_j = 18\), then we add 1 to \(U_i\).

The Gehan statistic is defined as

\[
U = \sum_{i=1}^{m+n} U_i \mathbf{1}_{\{i \text{ in group 0}\}}
\]

\[
= W
\]

\(U\) has mean 0 and variance

\[
\text{var}(U) = \frac{mn}{(m + n)(m + n - 1)} \sum_{i=1}^{m+n} U_i^2
\]
Example from Lee:

Group 0: 15, 18, 19, 19, 20

Group 1: 16+, 18+, 20+, 23, 24+

<table>
<thead>
<tr>
<th>Time</th>
<th>Group</th>
<th>$U_i$</th>
<th>$U_i^2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>15</td>

**this is Gehan’s test**
Notes about SAS Wilcoxon Test:
SAS calculates the Wilcoxon as $-U$ instead of $U$, probably so that the sign of the test statistic is consistent with the logrank.

SAS gets something slightly different for the variance, and this does not seem to depend on whether there are ties.

For example, the hypothetical dataset on p.6 without ties yields $U = -15$ and $\sum U_i^2 = 182$, so

$$Var(U) = \frac{(5)(5)(182)}{(10)(9)} = 50.56 \quad \text{and} \quad \chi^2 = \frac{(-15)^2}{50.56} = 4.45$$

while SAS gives the following:

Rank Statistics

<table>

Obtaining the Wilcoxon test using Stata

Use the `sts test` statement, with the appropriate option

```stata
    sts test varlist [if exp] [in range]
        [, [logrank|wilcoxon|cox] strata(varlist) detail
            mat(matname1 matname2) notitle noshow ]
```

`logrank`, `wilcoxon`, and `cox` specify which test of equality is desired.
`logrank` is the default, and `cox` yields a likelihood ratio test under a cox model.

Example: (leukemia data)

```
. stset remiss status
. sts test trt, wilcoxon
```

Wilcoxon (Breslow) test for equality of survivor functions

```
          | Events
trt    | observed  | expected  | Sum of ranks |
-----|-----------|-----------|--------------|
   0  |    21     |  10.75    |        271   |
   1  |     9     |  19.25    |       -271   |
Total |    30     |  30.00    |           0  |

    chi2(1) =    13.46
    Pr>chi2 =    0.0002
```
Generalized Wilcoxon
(Peto & Peto, Prentice)

Assign the following scores:
For a death at $t$:  
$$\hat{S}(t+) + \hat{S}(t-) - 1$$
For a censoring at $t$:  
$$\hat{S}(t+) - 1$$

The test statistic is $\sum(scores)$ for group 0.

<table>
<thead>
<tr>
<th>Time</th>
<th>Group</th>
<th>$d_j$</th>
<th>$r_j$</th>
<th>$\hat{S}(t+)$</th>
<th>score $w_j$</th>
</tr>
</thead>
<tbody>
<tr>
<td>15</td>
<td>0</td>
<td>1</td>
<td>10</td>
<td>0.900</td>
<td>0.900</td>
</tr>
<tr>
<td>16+</td>
<td>1</td>
<td>0</td>
<td>9</td>
<td>0.900</td>
<td>-0.100</td>
</tr>
<tr>
<td>18</td>
<td>0</td>
<td>1</td>
<td>8</td>
<td>0.788</td>
<td>0.688</td>
</tr>
<tr>
<td>18+</td>
<td>1</td>
<td>0</td>
<td>7</td>
<td>0.788</td>
<td>-0.212</td>
</tr>
<tr>
<td>19</td>
<td>0</td>
<td>2</td>
<td>6</td>
<td>0.525</td>
<td>0.313</td>
</tr>
<tr>
<td>20</td>
<td>0</td>
<td>1</td>
<td>4</td>
<td>0.394</td>
<td>-0.081</td>
</tr>
<tr>
<td>20+</td>
<td>1</td>
<td>0</td>
<td>3</td>
<td>0.394</td>
<td>-0.606</td>
</tr>
<tr>
<td>23</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>0.197</td>
<td>-0.409</td>
</tr>
<tr>
<td>24+</td>
<td>1</td>
<td>0</td>
<td>1</td>
<td>0.197</td>
<td>-0.803</td>
</tr>
</tbody>
</table>

$$\sum w_j \mathbf{1}_{\{j \text{ in group 0}\}} = 0.900 + 0.688 + 2 \times (0.313) + (-0.081) = 2.13$$

$$Var(S) = \frac{n_0n_1 \sum_{j=1}^{n} w_j^2}{n(n-1)} = 0.765$$

so  
$$Z = \frac{2.13}{0.765} = 2.433$$
The Tarone-Ware class of tests:

This general class of tests is like the logrank test, but adds weights \( w_j \). The logrank test, Wilcoxon test, and Peto-Prentice Wilcoxon are included as special cases.

\[
\chi^2_{tw} = \frac{\sum_{j=1}^{K} w_j(d_{1j} - r_{1j} \cdot d_j / r_j))^2}{\sum_{l=1}^{K} \frac{w_j^2 r_{1j} r_{0j} d_j (r_j - d_j)}{r_j^2 (r_j - 1)}}
\]

<table>
<thead>
<tr>
<th>Test</th>
<th>Weight ( w_j )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Logrank</td>
<td>( w_j = 1 )</td>
</tr>
<tr>
<td>Gehan’s Wilcoxon</td>
<td>( w_j = r_j )</td>
</tr>
<tr>
<td>Peto/Prentice</td>
<td>( w_j = n\bar{S}(t_j) )</td>
</tr>
<tr>
<td>Fleming-Harrington</td>
<td>( w_j = [\hat{S}(t_j)]^\alpha )</td>
</tr>
<tr>
<td>Tarone-Ware</td>
<td>( w_j = \sqrt{r_j} )</td>
</tr>
</tbody>
</table>

Note: these weights \( w_j \) are not the same as the scores \( w_j \) we’ve been talking about earlier, and they apply to the CMH-type form of the test statistic rather than \( \sum(scores) \) over a single treatment group.
Which test should we used?

**CMH-type or Linear Rank?**
If there are not a high proportion of ties, then it doesn’t really matter since:

- The two Wilcoxon are similar to each other
- The two logrank tests are similar to each other

Note: personally, I tend to use the CMH-type test, which you get with the `strata` statement in SAS and the `test` statement in STATA.

**Logrank or Wilcoxon?**

- Both tests have the right Type I power for testing the null hypothesis of equal survival, \( H_0 : S_1(t) = S_2(t) \)
- The choice of which test may therefore depend on the alternative hypothesis, which will drive the power of the test.
• The Wilcoxon is sensitive to early differences between survival, while the logrank is sensitive to later ones. This can be seen by the relative weights they assign to the test statistic:

\[
\text{LOGRANK numerator} = \sum_j (o_j - e_j)
\]

\[
\text{WILCOXON numerator} = \sum_j r_j (o_j - e_j)
\]

• The logrank is most powerful under the assumption of proportional hazards, which implies an alternative in terms of the survival functions of \( H_a : S_1(t) = [S_2(t)]^\alpha \)

• The Wilcoxon has high power when the failure times are lognormally distributed, with equal variance in both groups but a different mean. It will turn out that this is the assumption of an accelerated failure time model.

• Both tests will lack power if the survival curves (or hazards) “cross”. However, that does not necessarily make them invalid!
Comparison between TEST and STRATA in SAS for 2 examples:

**P-sample and stratified logrank tests**

We have been discussing two sample problems. In practice, more complex settings often arise:

- There are more than two treatments or groups, and the question of interest is whether the groups differ from each other.

- We are interested in a comparison between two groups, but we wish to adjust for another factor that may confound the analysis.

- We want to adjust for lots of covariates.

We will first talk about comparing the survival distributions between more than 2 groups, and then about adjusting for other covariates.
**P-sample logrank**

Suppose we observe data from $P$ different groups, and the data from group $p$ ($p = 1, \ldots, P$) are:

$$(X_{p1}, \delta_{p1}) \cdots (X_{pn_p}, \delta_{pn_p})$$

We now construct a $(P \times 2)$ table at each of the $K$ distinct death times, and compare the death rates between the $P$ groups, conditional on the number at risk.

Let $t_1, \ldots, t_K$ represent the $K$ ordered, distinct death times. At the $j$-th death time, we have the following table:

<table>
<thead>
<tr>
<th>Group</th>
<th>Die/Fail</th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Yes</td>
<td>No</td>
<td>Total</td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>$d_{1j}$</td>
<td>$r_{1j} - d_{1j}$</td>
<td>$r_{1j}$</td>
<td></td>
</tr>
<tr>
<td>\vdots</td>
<td>\vdots</td>
<td>\vdots</td>
<td>\vdots</td>
<td></td>
</tr>
<tr>
<td>$P$</td>
<td>$d_{pj}$</td>
<td>$r_{pj} - d_{pj}$</td>
<td>$r_{pj}$</td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>$d_j$</td>
<td>$r_j - d_j$</td>
<td>$r_j$</td>
<td></td>
</tr>
</tbody>
</table>

where $d_{pj}$ is the number of deaths in group $p$ at the $j$-th death time, and $r_{pj}$ is the number at risk at that time.

The tables are then combined using the CMH approach.
If we were just focusing on this one table, then a $\chi^2_{(P-1)}$ test statistic could be constructed through a comparison of “o”’s and “e”’s, like before.

**Example:** Toxicity in a clinical trial with 3 treatments

<table>
<thead>
<tr>
<th>GROUP</th>
<th>TOXICITY</th>
</tr>
</thead>
<tbody>
<tr>
<td>Frequency</td>

Formal Calculations:

Let $O_j = (d_{1j}, \ldots, d_{(P-1)j})^T$ be a vector of the observed number of failures in groups 1 to $(P - 1)$, respectively, at the $j$-th death time. Given the risk sets $r_{1j}, \ldots, r_{Pj}$, and the fact that there are $d_j$ deaths, then $O_j$ has a distribution like a multivariate version of the Hypergeometric. $O_j$ has mean:

$$E_j = \left( \frac{d_j r_{1j}}{r_j}, \ldots, \frac{d_j r_{(P-1)j}}{r_j} \right)^T$$

and variance covariance matrix:

$$V_j = \begin{pmatrix}
  v_{11j} & v_{12j} & \cdots & v_{1(P-1)j} \\
  v_{21j} & v_{22j} & \cdots & v_{2(P-1)j} \\
  \vdots & \vdots & \ddots & \vdots \\
  v_{(P-1)1j} & v_{(P-1)2j} & \cdots & v_{(P-1)(P-1)j}
\end{pmatrix}$$

where the $\ell$-th diagonal element is:

$$v_{\ell\ell j} = r_{\ell j}(r_j - r_{\ell j})d_j(r_j - d_j)/[r_j^2(r_j - 1)]$$

and the $\ell m$-th off-diagonal element is:

$$v_{\ell m j} = r_{\ell j}r_{m j}d_j(r_j - d_j)/[r_j^2(r_j - 1)]$$
The resulting $\chi^2$ test for a single $(P \times 1)$ table would have $(P-1)$ degrees and is constructed as follows:

$$(O_j - E_j)^T V_j^{-1} (O_j - E_j)$$

**Generalizing to K tables**

Analogous to what we did for the two sample logrank, we replace the $O_j$, $E_j$ and $V_j$ with the sums over the $K$ distinct death times. That is, let $O = \sum_{j=1}^{k} O_j$, $E = \sum_{j=1}^{k} E_j$, and $V = \sum_{j=1}^{k} V_j$. Then, the test statistic is:

$$(O - E)^T V^{-1} (O - E)$$
Example:
Time taken to finish a test with 3 different noise distractions. All tests were stopped after 12 minutes.

Note: do not use TEST in SAS PROC LIFETEST if you want a $P$-sample logrank. TEST will interpret the group variable as a measured covariate (i.e., either ordinal or continuous).

In other words, you will get a trend test with only 1 degree of freedom, rather than a $P$-sample test with $(p-1)$ df.

For example, here’s what we get if we use the TEST statement on the noise example:

```sas
proc lifetest data=noise;
  time testtime*finish(0);
  test group;
run;
```

**The Stratified Logrank**

Sometimes, even though we are interested in comparing two groups (or maybe $P$ groups), we know there are other factors that also affect the outcome. It would be useful to adjust for these other factors in some way.

**Example:** For the nursing home data, a logrank test comparing length of stay for those under and over 85 years of age suggests a significant difference ($p=0.03$).

However, we know that gender has a strong association with length of stay, and also age. Hence, it would be a good idea to STRATIFY the analysis by gender when trying to assess the age effect.

A stratified logrank allows one to compare groups, but allows the shapes of the hazards of the different groups to differ across strata. It makes the assumption that the group 1 vs group 2 hazard ratio is constant across strata.

In other words: $\frac{\lambda_{1s}(t)}{\lambda_{2s}(t)} = \theta$ where $\theta$ is constant over the strata ($s = 1, \ldots, S$).

This method of adjusting for other variables is not as flexible as that based on a modelling approach.
General setup for the stratified logrank:

Suppose we want to assess the association between survival and a factor (call this $X$) that has two different levels. Suppose however, that we want to stratify by a second factor, that has $S$ different levels.

First, divide the data into $S$ separate groups. Within group $s$ ($s = 1, ..., S$), proceed as though you were constructing the logrank to assess the association between survival and the variable $X$. That is, let $t_{1s}, ..., t_{K_s s}$ represent the $K_s$ ordered, distinct death times in the $s$-th group.

At the $j$-th death time in group $s$, we have the following table:

<table>
<thead>
<tr>
<th></th>
<th>Die/Fail</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>$X$</td>
<td>Yes</td>
<td>No</td>
<td>Total</td>
</tr>
<tr>
<td>1</td>
<td>$d_{s1j}$</td>
<td>$r_{s1j} - d_{s1j}$</td>
<td>$r_{s1j}$</td>
</tr>
<tr>
<td>2</td>
<td>$d_{s2j}$</td>
<td>$r_{s2j} - d_{s2j}$</td>
<td>$r_{s2j}$</td>
</tr>
<tr>
<td>Total</td>
<td>$d_{sj}$</td>
<td>$r_{sj} - d_{sj}$</td>
<td>$r_{sj}$</td>
</tr>
</tbody>
</table>
Let $O_s$ be the sum of the “o”s obtained by applying the logrank calculations in the usual way to the data from group $s$. Similarly, let $E_s$ be the sum of the “e”s, and $V_s$ be the sum of the “v”s.

The **stratified logrank** is

$$Z = \frac{\sum_{s=1}^{S}(O_s - E_s)}{\sqrt{\sum_{s=1}^{S}(V_s)}}$$
Stratified logrank using Stata:

```
. use nurshome
. gen age1=0
. replace age1=1 if age>85
. sts test age1, strata(gender)
   
   failure _d:  cens
   analysis time _t:  los
```

Modeling of Survival Data

Now we will explore the relationship between survival and explanatory variables by modeling. In this class, we consider two broad classes of regression models:

- **Proportional Hazards (PH) models**

\[
\lambda(t; Z) = \lambda_0(t)\Psi(Z)
\]

Most commonly, we write the second term as:

\[
\Psi(Z) = e^{\beta Z}
\]

Suppose \( Z = 1 \) for treated subjects and \( Z = 0 \) for untreated subjects. Then this model says that the hazard is increased by a factor of \( e^\beta \) for treated subjects versus untreated subjects (\( e^\beta \) might be < 1).

This is an example of a **semi-parametric** model.

- **Accelerated Failure Time (AFT) models**

\[
\log(T) = \mu + \beta Z + \sigma w
\]

where \( w \) is an “error distribution”. Typically, we place a **parametric** assumption on \( w \):

- exponential, Weibull, Gamma
- lognormal
Covariates:

In general, $\mathbf{Z}$ is a vector of covariates of interest.

$\mathbf{Z}$ may include:
- continuous factors (eg, age, blood pressure),
- discrete factors (gender, marital status),
- possible interactions (age by sex interaction)

Discrete Covariates:

Just as in standard linear regression, if we have a discrete covariate $A$ with $a$ levels, then we will need to include $(a - 1)$ dummy variables $(U_1, U_2, \ldots, U_a)$ such that $U_j = 1$ if $A = j$. Then

$$\lambda_i(t) = \lambda_0(t) \exp(\beta_2 U_2 + \beta_3 U_3 + \cdots + \beta_a U_a)$$

(In the above model, the subgroup with $A = 1$ or $U_1 = 1$ is the reference group.)

Interactions:

Two factors, $A$ and $B$, interact if the hazard of death depends on the combination of levels of $A$ and $B$.

We usually follow the principle of hierarchical models, and only include interactions if all of the corresponding main effects are also included.
The example I just gave was based on a proportional hazards model, but the description of the types of covariates we might want to include in our model applies to both the AFT and PH model.

We’ll start out by focusing on the Cox PH model, and address some of the following questions:

- What does the term \( \lambda_0(t) \) mean?
- What’s “proportional” about the PH model?
- How do we estimate the parameters in the model?
- How do we interpret the estimated values?
- How can we construct tests of whether the covariates have a significant effect on the distribution of survival times?
- How do these tests compare to the logrank test or the Wilcoxon test?
The Cox Proportional Hazards model

\[ \lambda(t; Z) = \lambda_0(t) \exp(\beta Z) \]

This is the most common model used for survival data.

Why?

- flexible choice of covariates
- fairly easy to fit
- standard software exists

Allison, Chapter 5
Cox and Oakes, Chapter 7
Kleinbaum, Chapter 3
Klein and Moeschberger, Chapters 8 & 9
Kalbfleisch and Prentice

Note: some books (like Collett and H & L) use \( h(t; X) \) as their standard notation for the hazard instead of \( \lambda(t; Z) \), and \( H(t) \) for the cumulative hazard instead of \( \Lambda(t) \).
Why do we call it proportional hazards?

Think of the first example, where $Z = 1$ for treated and $Z = 0$ for control. Then if we think of $\lambda_1(t)$ as the hazard rate for the treated group, and $\lambda_0(t)$ as the hazard for control, then we can write:

$$\lambda_1(t) = \lambda(t; Z = 1) = \lambda_0(t) \exp(\beta Z)$$

$$= \lambda_0(t) \exp(\beta)$$

This implies that the ratio of the two hazards is a constant, $\phi$, which does NOT depend on time, $t$. In other words, the hazards of the two groups remain proportional over time.

$$\phi = \frac{\lambda_1(t)}{\lambda_0(t)} = e^\beta$$

$\phi$ is referred to as the hazard ratio.

What is the interpretation of $\beta$ here?
The Baseline Hazard Function

In the example of comparing two treatment groups, $\lambda_0(t)$ is the hazard rate for the control group.

In general, $\lambda_0(t)$ is called the **baseline hazard function**, and reflects the underlying hazard for subjects with all covariates $Z_1, ..., Z_p$ equal to 0 (i.e., the “reference group”).

The general form is:

$$\lambda(t; Z) = \lambda_0(t) \exp(\beta_1 Z_1 + \beta_2 Z_2 + \cdots + \beta_p Z_p)$$

So when we substitute all of the $Z_j$’s equal to 0, we get:

$$\lambda(t, Z = 0) = \lambda_0(t) \exp(\beta_1 \cdot 0 + \beta_2 \cdot 0 + \cdots + \beta_p \cdot 0)$$

$$= \lambda_0(t)$$

In the general case, we think of the $i$-th individual having a set of covariates $Z_i = (Z_{1i}, Z_{2i}, ..., Z_{pi})$, and we model their hazard rate as some multiple of the baseline hazard rate:

$$\lambda_i(t, Z_i) = \lambda_0(t) \exp(\beta_1 Z_{1i} + \cdots + \beta_p Z_{pi})$$
This means we can write the log of the hazard ratio for the $i$-th individual to the reference group as:

$$
\log \left( \frac{\lambda_i(t)}{\lambda_0(t)} \right) = \beta_1 Z_{1i} + \beta_2 Z_{2i} + \cdots + \beta_p Z_{pi}
$$

**The Cox Proportional Hazards model is a linear model for the log of the hazard ratio**

One of the biggest advantages of the framework of the Cox PH model is that we can estimate the parameters $\beta$ which reflect the effects of treatment and other covariates without having to make any assumptions about the form of $\lambda_0(t)$.

In other words, we don’t have to assume that $\lambda_0(t)$ follows an exponential model, or a Weibull model, or any other particular parametric model.

That’s what makes the model *semi-parametric*.

**Questions:**

1. Why don’t we just model the hazard ratio, \( \phi = \frac{\lambda_i(t)}{\lambda_0(t)} \), directly as a linear function of the covariates $Z$?

2. Why doesn’t the model have an intercept?
How do we estimate the model parameters?

The basic idea is that under PH, information about $\beta$ can be obtained from the relative orderings (i.e., ranks) of the survival times, rather than the actual values. Why?

Suppose $T$ follows a PH model:

$$\lambda(t; Z) = \lambda_0(t)e^{\beta Z}$$

Now consider $T^* = g(T)$, where $g$ is a monotonic increasing function. We can show that $T^*$ also follows the PH model, with the same multiplier, $e^{\beta Z}$.

Therefore, when we consider likelihood methods for estimating the model parameters, we only have to worry about the ranks of the survival times.
Likelihood Estimation for the PH Model

Kalbfleisch and Prentice derive a likelihood involving only \( \beta \) and \( Z \) (not \( \lambda_0(t) \)) based on the marginal distribution of the ranks of the observed failure times (in the absence of censoring).

Cox (1972) derived the same likelihood, and generalized it for censoring, using the idea of a partial likelihood.

Suppose we observe \((X_i, \delta_i, Z_i)\) for individual \(i\), where

- \(X_i\) is a censored failure time random variable
- \(\delta_i\) is the failure/censoring indicator (1=fail, 0=censor)
- \(Z_i\) represents a set of covariates

The covariates may be continuous, discrete, or time-varying.
Suppose there are $K$ distinct failure (or death) times, and let $\tau_1, ..., \tau_K$ represent the $K$ ordered, distinct death times.

**For now, assume there are no tied death times.**

Let $\mathcal{R}(t) = \{ i : x_i \geq t \}$ denote the set of individuals who are “at risk” for failure at time $t$.

**More about risk sets:**

- I will refer to $\mathcal{R}(\tau_j)$ as the risk set at the $j$th failure time
- I will refer to $\mathcal{R}(X_i)$ as the risk set at the failure time of individual $i$
- There will still be $r_j$ individuals in $\mathcal{R}(\tau_j)$.
- $r_j$ is a number, while $\mathcal{R}(\tau_j)$ identifies the actual subjects at risk
What is the partial likelihood?

Intuitively, it is a product over the set of observed death times of the conditional probabilities of seeing the observed deaths, given the set of individuals at risk at those times.

At each death time $\tau_j$, the contribution to the likelihood is:

$$L_j(\beta) = Pr(\text{individual } j \text{ fails} | \text{1 failure from } \mathcal{R}(\tau_j))$$

$$= \frac{Pr(\text{individual } j \text{ fails} | \text{ at risk at } \tau_j)}{\sum_{\ell \in \mathcal{R}(\tau_j)} Pr(\text{individual } \ell \text{ fails} | \text{ at risk at } \tau_j)}$$

$$= \frac{\lambda(\tau_j; Z_j)}{\sum_{\ell \in \mathcal{R}(\tau_j)} \lambda(\tau_j; Z_\ell)}$$

Under the PH assumption, $\lambda(t; Z) = \lambda_0(t)e^{\beta Z}$, so we get:

$$L^{\text{partial}}(\beta) = \prod_{j=1}^{K} \frac{\lambda_0(\tau_j)e^{\beta Z_j}}{\sum_{\ell \in \mathcal{R}(\tau_j)} \lambda_0(\tau_j)e^{\beta Z_\ell}}$$

$$= \prod_{j=1}^{K} \frac{e^{\beta Z_j}}{\sum_{\ell \in \mathcal{R}(\tau_j)} e^{\beta Z_\ell}}$$
Another derivation:

In general, the likelihood contributions for censored data fall into two categories:

- **Individual is censored at** $X_i$:
  \[
  L_i(\beta) = S(X_i) = \exp[- \int_0^{X_i} \lambda_i(u)du]
  \]

- **Individual fails at** $X_i$:
  \[
  L_i(\beta) = S(X_i) \lambda_i(X_i) = \lambda_i(X_i) \exp[- \int_0^{X_i} \lambda_i(u)du]
  \]

Thus, everyone contributes $S(X_i)$ to the likelihood, and only those who fail contribute $\lambda_i(X_i)$.

This means we get a total likelihood of:

\[
L(\beta) = \prod_{i=1}^{n} \lambda_i(X_i)^{\delta_i} \exp[- \int_0^{X_i} \lambda_i(u)du]
\]

The above likelihood holds for all censored survival data, with general hazard function $\lambda(t)$. In other words, we haven’t used the Cox PH assumption at all yet.
Now, let’s multiply and divide by the term $\left[\sum_{j \in R(X_i)} \lambda_i(X_i)\right]^{\delta_i}$:

$$L(\beta) = \prod_{i=1}^{n} \left[ \frac{\lambda_i(X_i)}{\sum_{j \in R(X_i)} \lambda_i(X_i)} \right]^{\delta_i} \left[ \sum_{j \in R(X_i)} \lambda_i(X_i) \right]^{\delta_i} \exp[-\int_{0}^{X_i} \lambda_i(u)du]$$

Cox (1972) argued that the first term in this product contained almost all of the information about $\beta$, while the second two terms contained the information about $\lambda_0(t)$, i.e., the baseline hazard.

If we just focus on the first term, then under the Cox PH assumption:

$$L(\beta) = \prod_{i=1}^{n} \left[ \frac{\lambda_i(X_i)}{\sum_{j \in R(X_i)} \lambda_i(X_i)} \right]^{\delta_i}$$

$$= \prod_{i=1}^{n} \left[ \frac{\lambda_0(X_i) \exp(\beta Z_i)}{\sum_{j \in R(X_i)} \lambda_0(X_i) \exp(\beta Z_j)} \right]^{\delta_i}$$

$$= \prod_{i=1}^{n} \left[ \frac{\exp(\beta Z_i)}{\sum_{j \in R(X_i)} \exp(\beta Z_j)} \right]^{\delta_i}$$

This is the partial likelihood defined by Cox. Note that it does not depend on the underlying hazard function $\lambda_0(\cdot)$. Cox recommends treating this as an ordinary likelihood for making inferences about $\beta$ in the presence of the nuisance parameter $\lambda_0(\cdot)$. 

179
A simple example:

<table>
<thead>
<tr>
<th>individual</th>
<th>$X_i$</th>
<th>$\delta_i$</th>
<th>$Z_i$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>9</td>
<td>1</td>
<td>4</td>
</tr>
<tr>
<td>2</td>
<td>8</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>3</td>
<td>6</td>
<td>1</td>
<td>7</td>
</tr>
<tr>
<td>4</td>
<td>10</td>
<td>1</td>
<td>3</td>
</tr>
</tbody>
</table>

Now let’s compile the pieces that go into the partial likelihood contributions at each failure time:

<table>
<thead>
<tr>
<th>ordered failure</th>
<th>time $X_i$</th>
<th>$\mathcal{R}(X_i)$</th>
<th>$i_j$</th>
<th>Likelihood contribution</th>
</tr>
</thead>
<tbody>
<tr>
<td>$j$</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>6</td>
<td>${1,2,3,4}$</td>
<td>3</td>
<td>$e^{7\beta}/[e^{4\beta} + e^{5\beta} + e^{7\beta} + e^{3\beta}]$</td>
</tr>
<tr>
<td>2</td>
<td>8</td>
<td>${1,2,4}$</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>9</td>
<td>${1,4}$</td>
<td>1</td>
<td>$e^{4\beta}/[e^{4\beta} + e^{3\beta}]$</td>
</tr>
<tr>
<td>4</td>
<td>10</td>
<td>${4}$</td>
<td>4</td>
<td>$e^{3\beta}/e^{3\beta} = 1$</td>
</tr>
</tbody>
</table>

The partial likelihood would be the product of these four terms.
Notes on the partial likelihood:

\[ L(\beta) = \prod_{j=1}^{n} \left[ \frac{e^{\beta Z_j}}{\sum_{\ell \in R(X_j)} e^{\beta Z_{\ell}}} \right]^{\delta_j} \]

\[ = \prod_{j=1}^{K} \frac{e^{\beta z_j}}{\sum_{\ell \in R(\tau_j)} e^{\beta z_{\ell}}} \]

where the product is over the \( K \) death (or failure) times.

- contributions only at the death times
- the partial likelihood is NOT a product of independent terms, but of conditional probabilities
- There are other choices besides \( \Psi(Z) = e^{\beta Z} \), but this is the most common and the one for which software is generally available.
Partial Likelihood inference

Inference can be conducted by treating the partial likelihood as though it satisfied all the regular likelihood properties.

The log-partial likelihood is:

$$\ell(\beta) = \log \left[ \frac{n}{\prod_{j=1}^{\delta_j} \sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right]$$

$$= \log \left[ \prod_{j=1}^{K} \frac{e^{\beta Z_j}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right]$$

$$= \sum_{j=1}^{K} \left[ \beta Z_j - \log \left[ \sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}} \right] \right]$$

$$= \sum_{j=1}^{K} l_j(\beta)$$

where $l_j$ is the log-partial likelihood contribution at the $j$-th ordered death time.
Suppose there is only one covariate ($\mathbf{\beta}$ is one-dimensional):

The **partial likelihood score equations** are:

$$U(\beta) = \frac{\partial}{\partial \beta} \ell(\beta) = \sum_{j=1}^{n} \delta_j \left[ Z_j - \frac{\sum_{\ell \in R(\tau_j)} Z_\ell e^{\beta Z_\ell}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_\ell}} \right]$$

We can express $U(\beta)$ intuitively as a sum of “observed” minus “expected” values:

$$U(\beta) = \frac{\partial}{\partial \beta} \ell(\beta) = \sum_{j=1}^{n} \delta_j (Z_j - \bar{Z}_j)$$

where $\bar{Z}_j$ is the “weighted average” of the covariate $Z$ over all the individuals in the risk set at time $\tau_j$. Note that $\beta$ is involved through the term $Z_j$.

The maximum partial likelihood estimators can be found by solving $U(\beta) = 0$. 
Analogous to standard likelihood theory, it can be shown (though not easily) that

\[
\frac{(\hat{\beta} - \beta)}{se(\hat{\beta})} \sim N(0, 1)
\]

The variance of \( \hat{\beta} \) can be obtained by inverting the second derivative of the partial likelihood,

\[
\text{var}(\hat{\beta}) \sim \left[ -\frac{\partial^2}{\partial \beta^2} \ell(\beta) \right]^{-1}
\]

From the above expression for \( U(\beta) \), we have:

\[
\frac{\partial^2}{\partial \beta^2} \ell(\beta) = \sum_{j=1}^{n} \delta_j \left[ \frac{-\sum_{\ell \in R(\tau_j)} (Z_j - \bar{Z}_j)^2 e^{\beta Z_\ell}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_\ell}} \right]
\]

Note:
The true variance of \( \hat{\beta} \) ends up being a function of \( \beta \), which is unknown. We calculate the “observed” information by substituting in our partial likelihood estimate of \( \beta \) into the above formula for the variance
Simple Example for 2-group comparison: (no ties)

**Group 0:**  \(4^+, 7, 8^+, 9, 10^+ \Rightarrow Z_i = 0\)

**Group 1:**  \(3, 5, 5^+, 6, 8^+ \Rightarrow Z_i = 1\)

<table>
<thead>
<tr>
<th>j</th>
<th>ordered failure</th>
<th>Number at risk</th>
<th>Likelihood contribution</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>time (X_i)</td>
<td>Group 0</td>
<td>Group 1</td>
</tr>
<tr>
<td>---</td>
<td>----------------</td>
<td>--------</td>
<td>--------</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>2</td>
<td>5</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>3</td>
<td>6</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>4</td>
<td>7</td>
<td>4</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>9</td>
<td>2</td>
<td>0</td>
</tr>
</tbody>
</table>

Again, we take the product over the likelihood contributions, then maximize to get the partial MLE for \(\beta\).

What does \(\beta\) represent in this case?
Notes

- The “observed” information matrix is generally used because in practice, people find it has better properties. Also, the “expected” is very hard to calculate.

- There is a nice analogy with the score and information matrices from more standard regression problems, except that here we are summing over observed death times, rather than individuals.

- Newton Raphson is used by many of the computer packages to solve the partial likelihood equations.
Fitting Cox PH model with Stata

Uses the “stcox” command.

First, try typing “help stcox”

Estimate Cox proportional hazards model

</tbody>
</table>

Notes:

- **The logrank test** = **score test from Proc phreg**!
  In general, the score test would be for all of the variables in the model, but in this case, we have only “trtmt”.

- Stata does not provide a score test in its output from the Cox model. However, the stcox command with the breslow option for ties yields the same LR test as the CMH-version logrank test from the sts test, cox command.
More Notes:

- The Cox Proportional hazards model has the advantage over a simple logrank test of giving us an estimate of the “risk ratio” (i.e., $\phi = \lambda_1(t)/\lambda_0(t)$). This is more informative than just a test statistic, and we can also form confidence intervals for the risk ratio.

- In this case, $\hat{\phi} = 0.221$, which can be interpreted to mean that the hazard for relapse among patients treated with 6-MP is less than 25% of that for placebo patients.

- From the `sts list` command in Stata or `PROC LIFETEST` in SAS, we were able to get estimates of the entire survival distribution $\hat{S}(t)$ for each treatment group; we can’t immediately get this from our Cox model without further assumptions. **Why not?**
Adjustments for ties
The proportional hazards model assumes a continuous hazard – ties are not possible. There are four proposed modifications to the likelihood to adjust for ties.

1. **Cox’s (1972) modification:** “discrete” method
2. **Peto-Breslow method**
3. **Efron’s (1977) method**
4. **Exact method (Kalbfleisch and Prentice)**
5. **Exact marginal method** (stata)

Some notation:
- $\tau_1, \ldots, \tau_K$ the $K$ ordered, distinct death times
- $d_j$ the number of failures at $\tau_j$
- $H_j$ the “history” of the entire data set, up to the $j$-th death or failure time, including the time of the failure, but not the identities of the $d_j$ who fail there.
- $i_{j1}, \ldots, i_{jd_j}$ the identities of the $d_j$ individuals who fail at $\tau_j$
(1) **Cox’s (1972) modification:** “discrete” method

Cox’s method assumes that if there are tied failure times, they truly happened at the same time. It is based on a discrete likelihood.

The **partial likelihood** is:

\[
L(\beta) = \prod_{j=1}^{K} \Pr(i_{j1}, \ldots, i_{jd_j} \text{ fail } | \ d_j \text{ fail at } \tau_j, \ \text{from } \mathcal{R})
\]

\[
= \prod_{j=1}^{K} \frac{\Pr(i_{j1}, \ldots, i_{jd_j} \text{ fail } | \ \text{in } \mathcal{R}(\tau_j))}{\sum_{\ell \in s(j,d_j)} \Pr(\ell_1, \ldots, \ell_{d_j} \text{ fail } | \ \text{in } \mathcal{R}(\tau_j))}
\]

\[
= \prod_{j=1}^{K} \frac{\exp(\beta Z_{i_{j1}}) \cdots \exp(\beta Z_{i_{jd_j}})}{\sum_{\ell \in s(j,d_j)} \exp(\beta Z_{\ell_1}) \cdots \exp(\beta Z_{\ell_{d_j}})}
\]

\[
= \prod_{j=1}^{K} \frac{\exp(\beta S_j)}{\sum_{\ell \in s(j,d_j)} \exp(\beta S_{j\ell})}
\]

where

- \( s(j, d_j) \) is the set of all possible sets of \( d_j \) individuals that can possibly be drawn from the risk set at time \( \tau_j \)
- \( S_j \) is the sum of the \( Z \)'s for all the \( d_j \) individuals who fail at \( \tau_j \)
- \( S_{j\ell} \) is the sum of the \( Z \)'s for all the \( d_j \) individuals in the \( \ell \)-th set drawn out of \( s(j, d_j) \)
What does this all mean??!!

Let’s modify our previous simple example to include ties.

**Simple Example (with ties)**

<table>
<thead>
<tr>
<th>Group 0: 4⁺, 6, 8⁺, 9, 10⁺</th>
<th>( Z_i = 0 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group 1: 3, 5, 5⁺, 6, 8⁺</td>
<td>( Z_i = 1 )</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Ordered failure time ( X_i )</th>
<th>Number at risk</th>
<th>Likelihood Contribution</th>
</tr>
</thead>
<tbody>
<tr>
<td>( j )</td>
<td>Group 0</td>
<td>Group 1</td>
</tr>
<tr>
<td>1</td>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>2</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>3</td>
<td>4</td>
<td>2</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>0</td>
</tr>
</tbody>
</table>

The tie occurs at \( t = 6 \), when \( \mathcal{R}(\tau_j) = \{ Z = 0 : (6, 8⁺), 9, 10⁺ \}, Z = 1 : (6, 8⁺) \}. Of the \( \binom{6}{2} = 15 \) possible pairs of subjects at risk at \( t=6 \), there are 6 pairs formed where both are from group 0 \( (S_j = 0) \), 8 pairs formed with one in each group \( (S_j = 1) \), and 1 pairs formed with both in group 1 \( (S_j = 2) \).

**Problem:** With large numbers of ties, the denominator can have many many terms and be difficult to calculate.
Breslow method: (default)

Breslow and Peto suggested replacing the term \( \sum_{\ell \in s(j, d_j)} e^{\beta S_{j\ell}} \)
in the denominator by the term \( \left( \sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}} \right)^{d_j} \), so that the
following modified partial likelihood would be used:

\[
L(\beta) = \prod_{j=1}^{K} \frac{e^{\beta S_j}}{\sum_{\ell \in s(j, d_j)} e^{\beta S_{j\ell}}} \approx \prod_{j=1}^{K} \frac{e^{\beta S_j}}{\left( \sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}} \right)^{d_j}}
\]

Justification:

Suppose individuals 1 and 2 fail from \( \{1, 2, 3, 4\} \) at time \( \tau_j \). Let \( \phi(i) \) be the hazard ratio for individual \( i \) (compared to baseline).

\[
\frac{e^{\beta S_j}}{\sum_{\ell \in s(j, d_j)} e^{\beta S_{j\ell}}} = \frac{\phi(1)}{\phi(1) + \phi(2) + \phi(3) + \phi(4)} \times \frac{\phi(2)}{\phi(2) + \phi(3) + \phi(4)} + \frac{\phi(2)}{\phi(1) + \phi(2) + \phi(3) + \phi(4)} \times \frac{\phi(1)}{\phi(1) + \phi(3) + \phi(4)}
\]

\[
\approx \frac{2\phi(1)\phi(2)}{[\phi(1) + \phi(2) + \phi(3) + \phi(4)]^2}
\]

The Peto (Breslow) approximation will break down when the number of ties are large relative to the size of the risk sets, and then tends to yield estimates of \( \beta \) which are biased toward 0.
**3) Efron’s (1977) method:**

Efron suggested an even closer approximation to the discrete likelihood:

\[
L(\beta) = \frac{\prod_{j=1}^{K} e^{\beta S_j}}{e^{\beta S_j} \left( \sum_{\ell \in R(\tau_j)} e^{\beta Z_\ell} + \frac{i-1}{d_j} \sum_{\ell \in D(\tau_j)} e^{\beta Z_\ell} \right)^{d_j}}
\]

Like the Breslow approximation, Efron’s method will yield estimates of \( \beta \) which are biased toward 0 when there are many ties.

However, Allison (1995) recommends the Efron approximation since it is much faster than the exact methods and tends to yield much closer estimates than the default Breslow approach.
(4) Exact method (Kalbfleisch and Prentice):
The “discrete” option that we discussed in (1) is an exact method based on a discrete likelihood (assuming that tied events truly ARE tied).

This second exact method is based on the continuous likelihood, under the assumption that if there are tied events, that is due to the imprecise nature of our measurement, and that there must be some *true* ordering.

All possible orderings of the tied events are calculated, and the probabilities of each are summed.

Example with 2 tied events (1,2) from riskset (1,2,3,4):

\[
\frac{e^{\beta S_j}}{\sum_{\ell \in s(j,d_j)} e^{\beta S_{j\ell}}} = \frac{e^{\beta S_1}}{e^{\beta S_1} + e^{\beta S_2} + e^{\beta S_3} + e^{\beta S_4}} \times \frac{e^{\beta S_2}}{e^{\beta S_2} + e^{\beta S_3} + e^{\beta S_4}} \\
+ \frac{e^{\beta S_2}}{e^{\beta S_1} + e^{\beta S_2} + e^{\beta S_3} + e^{\beta S_4}} \times \frac{e^{\beta S_1}}{e^{\beta S_1} + e^{\beta S_2} + e^{\beta S_3} + e^{\beta S_4}}
\]
Bottom Line: Implications of Ties
(See Allison (1995), p.127-137)

(1) **When there are no ties**, all options give *exactly* the same results.

(2) **When there are only a few ties**, it won’t make much difference which method is used. However, since the exact methods won’t take much extra computing time, you might as well use one of them.

(3) **When there are many ties** (relative to the number at risk), the Breslow option (default) performs poorly (Farewell & Prentice, 1980; Hsieh, 1995). Both of the approximate methods, Breslow and Efron, yield coefficients that are attenuated (biased toward 0).

(4) **The choice of which exact method to use** should be based on substantive grounds - are the tied event times truly tied? ...or are they the result of imprecise measurement?

(5) **Computing time of exact methods** is much longer than that of the approximate methods. However, in most cases it will still be less than 30 seconds even for the exact methods.

(6) **Best approximate method** - the Efron approximation nearly always works better than the Breslow method, with no increase in computing time, so use this option if exact methods are too computer-intensive.
Example: The fecundability study
Women who had recently given birth (or had tried to get pregnant for at least a year) were asked to recall how long it took them to become pregnant, and whether or not they smoked during that time. The outcome of interest is time to pregnancy (measured in menstrual cycles).

```
data fecund;

For this particular dataset, does it seem like it would be important to consider the effect of tied failure times? Which method would be best?
Stata Commands for PH Model with Ties:

Stata also offers four options for adjustments with tied data:

- **breslow** (default)
- **efron**
- **exactp** (same as the “discrete” option in SAS)
- **exactm** - an exact marginal likelihood calculation (different than the “exact” option in SAS)

Fecundability Data Example:

```
. stcox smoker, efron nohr

  failure _d: status
  analysis time _t: cycle

Iteration 0:  log likelihood =  -3113.5313
Iteration 1:  log likelihood =  -3107.3102
Iteration 2:  log likelihood =  -3107.2464
Iteration 3:  log likelihood =  -3107.2464
Refining estimates:
Iteration 0:  log likelihood =  -3107.2464

Cox regression -- Efron method for ties

No. of subjects =      586  Number of obs      =      586
No. of failures =      567  Time at risk =     1844
LR chi2(1)    =     12.57
Log likelihood =  -3107.2464  Prob > chi2 =    0.0004

A special case: the two-sample problem

Previously, we derived the logrank test from an intuitive perspective, assuming that we have \((X_{01}, \delta_{01}) \ldots (X_{0n_0}, \delta_{0n_0})\) from group 0 and \((X_{11}, \delta_{11}), \ldots, (X_{1n_1}, \delta_{1n_1})\) from group 1.

Just as a \(\chi^2\) test for binary data can be derived from a logistic model, we will see here that the logrank test can be derived as a special case of the Cox Proportional Hazards model.

First, let's re-define our notation in terms of \((X_i, \delta_i, Z_i)\):

\[
(X_{01}, \delta_{01}), \ldots, (X_{0n_0}, \delta_{0n_0}) \implies (X_1, \delta_1, 0), \ldots, (X_{n_0}, \delta_{n_0}, 0) \\
(X_{11}, \delta_{11}), \ldots, (X_{1n_1}, \delta_{1n_1}) \implies (X_{n_0+1}, \delta_{n_0+1}, 1), \ldots, (X_{n_0+n_1}, \delta_{n_0+n_1}, 1)
\]

In other words, we have \(n_0\) rows of data \((X_i, \delta_i, 0)\) for the group 0 subjects, then \(n_1\) rows of data \((X_i, \delta_i, 1)\) for the group 1 subjects.

Using the proportional hazards formulation, we have

\[
\lambda(t; Z) = \lambda_0(t) e^{\beta Z}
\]

**Group 0 hazard:** \(\lambda_0(t)\)  
**Group 1 hazard:** \(\lambda_0(t) e^{\beta}\)
The log-partial likelihood is:

\[
\log L(\beta) = \log \left[ \prod_{j=1}^{K} \frac{e^{\beta Z_j}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right]
\]

\[
= \sum_{j=1}^{K} \left[ \beta Z_j - \log \left( \sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}} \right) \right]
\]

Taking the derivative with respect to \( \beta \), we get:

\[
U(\beta) = \frac{\partial}{\partial \beta} \ell(\beta)
\]

\[
= \sum_{j=1}^{n} \delta_j \left[ Z_j - \frac{\sum_{\ell \in R(\tau_j)} Z_{\ell} e^{\beta Z_{\ell}}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right]
\]

\[
= \sum_{j=1}^{n} \delta_j (Z_j - \bar{Z}_j)
\]

where \( \bar{Z}_j = \frac{\sum_{\ell \in R(\tau_j)} Z_{\ell} e^{\beta Z_{\ell}}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \)

\( U(\beta) \) is called the “score”.
As we discussed earlier in the class, one useful form of a likelihood-based test is the score test. This is obtained by using the score $U(\beta)$ evaluated at $H_o$ as a test statistic.

Let’s look more closely at the form of the score:

\begin{align*}
\delta_j Z_j & \quad \text{observed number of deaths in group 1 at } \tau_j \\
\delta_j \bar{Z}_j & \quad \text{expected number of deaths in group 1 at } \tau_j
\end{align*}

**Why?** Under $H_0 : \beta = 0$, $\bar{Z}_j$ is simply the number of individuals from group 1 in the risk set at time $\tau_j$ (call this $r_{1j}$), divided by the total number in the risk set at that time (call this $r_j$). Thus, $\bar{Z}_j$ approximates the probability that given there is a death at $\tau_j$, it is from group 1.

**Thus, the score statistic is of the form:**

$$
\sum_{j=1}^{n} (O_j - E_j)
$$

When there are ties, the likelihood has to be replaced by one that allows for ties.

**In SAS or Stata:**

- `discrete/exactp` → Mantel-Haenszel logrank test
- `breslow` → linear rank version of the logrank test
I already showed you the equivalence of the linear rank log-rank test and the Breslow (default) Cox PH model in SAS (p.24-25)

Here is the output from SAS for the leukemia data using the **method=discrete** option:

More on the Cox PH model

I. Confidence intervals and hypothesis tests
   – Two methods for confidence intervals
   – Wald tests and likelihood ratio tests
   – Interpretation of parameter estimates
   – An example with real data from an AIDS clinical trial

II. Predicted survival under proportional hazards

III. Predicted medians and P-year survival
I. Constructing Confidence intervals and tests for the Hazard Ratio (see H & L 4.2, Collett 3.4):

Many software packages provide estimates of $\beta$, but the hazard ratio $HR = \exp(\beta)$ is usually the parameter of interest.

We can use the delta method to get standard errors for $\exp(\hat{\beta})$:

$$Var(\hat{HR}) = Var(\exp(\hat{\beta})) = \exp(2\hat{\beta})Var(\hat{\beta})$$

**Constructing confidence intervals for $\exp(\beta)$**

**Two options:** (assuming that $\beta$ is a scalar)

I. Using $se(\exp(\hat{\beta})$ obtained above via the delta method as $se(\exp(\hat{\beta}) = \sqrt{Var(\exp(\hat{\beta}))}$, calculate the endpoints as:

$$[L, U] = [\hat{OR} - 1.96 se(\hat{OR}), \hat{OR} + 1.96 se(\hat{OR})]$$

II. Form a confidence interval for $\hat{\beta}$, and then exponentiate the endpoints.

$$[L, U] = [e^{\hat{\beta} - 1.96 se(\hat{\beta})}, e^{\hat{\beta} + 1.96 se(\hat{\beta})}]$$

**Which approach do you think would be the most preferable?**
Hypothesis Tests:

For each covariate of interest, the null hypothesis is

\[ H_o : HR_j = 1 \iff \beta_j = 0 \]

A Wald test\(^2\) of the above hypothesis is constructed as:

\[ Z = \frac{\hat{\beta}_j}{se(\hat{\beta}_j)} \quad \text{or} \quad \chi^2 = \left( \frac{\hat{\beta}_j}{se(\hat{\beta}_j)} \right)^2 \]

This test for \( \beta_j = 0 \) assumes that all other terms in the model are held fixed.

Note: if we have a factor \( A \) with \( a \) levels, then we would need to construct a \( \chi^2 \) test with \( (a - 1) \) df, using a test statistic based on a quadratic form:

\[ \chi^2_{(a-1)} = \beta_A' Var(\beta_A)^{-1} \beta_A \]

where \( \beta_A = (\beta_2, \ldots, \beta_a)' \) are the \( (a - 1) \) coefficients corresponding to \( Z_2, \ldots, Z_a \) (or \( Z_1, \ldots, Z_{a-1} \), depending on the reference group).

---

\(^2\)The first follows a normal distribution, and the second follows a \( \chi^2 \) with 1 df. STATA gives the Z statistic, while SAS gives the \( \chi^2 \) test statistic (the p-values are also given, and don’t depend on which form, Z or \( \chi^2 \), is provided)
Likelihood Ratio Tests:

Suppose there are \((p + q)\) explanatory variables measured:

\[ Z_1, \ldots, Z_p, Z_{p+1}, \ldots, Z_{p+q} \]

and proportional hazards are assumed.

Consider the following models:

- **Model 1:** (contains only the first \(p\) covariates)
  \[
  \frac{\lambda_i(t, Z)}{\lambda_0(t)} = \exp(\beta_1 Z_1 + \cdots + \beta_p Z_p)
  \]

- **Model 2:** (contains all \((p + q)\) covariates)
  \[
  \frac{\lambda_i(t, Z)}{\lambda_0(t)} = \exp(\beta_1 Z_1 + \cdots + \beta_{p+q} Z_{p+q})
  \]

These are *nested* models. For such nested models, we can construct a **likelihood ratio** test of

\[ H_0 : \beta_{p+1} = \cdots = \beta_{p+q} = 0 \]

as:

\[
\chi^2_{LR} = -2 \left[ \log(\hat{L}(1)) - \log(\hat{L}(2)) \right]
\]

Under \(H_o\), this test statistic is approximately distributed as \(\chi^2\) with \(q\) df.
Some examples using the Stata `stcox` command:  

**Model 1:**

```
. use mac
. stset mactime macstat
. stcox karnof rif clari, nohr
   
   failure _d:  macstat
   analysis time _t:  mactime
```

Cox regression -- Breslow method for ties

| clari         | .2760775 | .2580215 | 1.070 | 0.285 | -.2296354 to .7817903 |
Model 2:

```
. stcox karnof rif clari cd4, nohr
    failure _d:  macstat
    analysis time _t:  mactime
```

Cox regression -- Breslow method for ties

|           | Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|-----------|-------|-----------|------|-----|----------------------|
| karnof    | -.0368538 | .0106652  | -3.456 | 0.001 | -.0577572 -.0159503 |
| rif       | .880338  | .2371111  | 3.713 | 0.000 | .4156089 1.345067    |
| clari     | .2530205 | .2583478  | 0.979 | 0.327 | -.253332 .7593729   |
| cd4       | -.0183553 | .0036839  | -4.983 | 0.000 | -.0255757 -.0111349 |

No. of subjects = 1151  Number of obs = 1151
No. of failures = 121
Time at risk = 489509
LR chi2(4) = 63.74
Log likelihood = -738.66225  Prob > chi2 = 0.0000
Notes:

- If we omit the `nohr` option, we will get the estimated hazard ratio along with 95% confidence intervals using Method II (i.e., forming a CI for the log HR (beta), and then exponentiating the bounds)

|   | _t | _d | Haz. Ratio | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|---|----|----|------------|-----------|-------|-------|---------------------|
|   |    |    | karnof     | .9638171  | .0102793| -3.456| 0.001               | .9438791 .9841762 |
|   |    |    | rif        | 2.411715  | .5718442| 3.713 | 0.000               | 1.515293 3.838444 |
|   |    |    | clari      | 1.28791   | .3327287| 0.979 | 0.327               | .7762102 2.136936 |
|   |    |    | cd4        | .9818121  | .0036169| -4.983| 0.000               | .9747486 .9889269 |

- We can also compute the hazard ratio ourselves, by exponentiating the coefficients:

\[
HR_{cd4} = \exp(-0.01835) = 0.98
\]

**Why is this HR so close to 1, and yet still highly significant?**

**What is the interpretation of this HR?**

- The likelihood ratio test for the effect of CD4 is twice the difference in minus log-likelihoods between the two models:

\[
\chi^2_{LR} = 2 \times (754.533 - (738.66)) = 31.74
\]

How does this test statistic compare to the Wald \( \chi^2 \) test?
In the mac study, there were three treatment arms (rif, clari, and the rif+clari combination). Because we have only included the rif and clari effects in the model, the combination therapy is the “reference” group.

We can conduct an overall test of treatment using the test command in Stata:

```
. test rif clari
( 1) rif = 0.0
( 2) clari = 0.0

         chi2( 2) =  17.01
    Prob > chi2 =  0.0002
```

for a 2 df Wald chi-square test of whether both treatment coefficients are equal to 0. This test command can be used to conduct an overall test for any number of effects.

The test command can also be used to test whether there is a difference between the rif and clari treatment arms:

```
. test rif=clari
( 1) rif - clari = 0.0

         chi2( 1) =   8.76
    Prob > chi2 =  0.0031
```
Some examples using SAS PROC PHREG

```sas
proc phreg data=alloi;
  model dthtime*dthstat(0)=mlogrna cd4grp1 cd4grp2 combther
       / risklimits;
  cd4level: test cd4grp1, cd4grp2;
  title1 'Proportional hazards regression model for time to Death';
  title2 'Baseline viral load and CD4 predictors';
proc phreg data=alloi;
  model dthtime*dthstat(0)=mlogrna cd4grp1 cd4grp2 combther decrs8 incrs8
       / risklimits;
  cd4level: test cd4grp1, cd4grp2;
  wk8resp: test decrs8, incrs8;
```

Notes:

- The “risklimits” option on the model statement provides 95% confidence intervals using Method II from page 2. (i.e., forming a CI for the log HR (beta), and then exponentiating the bounds)
- The “test” statement has the following form:

  **Label**: test varname1, varname2, ..., varnamek;

  for a $k$ df Wald chi-square test of whether the $k$ coefficients are all equal to 0.
- We can use the same approach described by Freedman to assess the effects of intermediate endpoints (incrs8, decrs8) on the treatment effect (i.e., assess their use as surrogate markers). The percentage of treatment effect explained, $\gamma$, is estimated by:

  $$\hat{\gamma} = 1 - \frac{\hat{\beta}_{trt,M2}}{\hat{\beta}_{trt,M1}}$$

  where M1 is the model without the intermediate endpoint and M2 is the model with the marker.

The percentage of treatment effect explained by including the RNA and CD4 response to treatment by Week 8 is:

$$\hat{\gamma} = 1 - \frac{-0.456}{-0.497} \approx 0.08$$

or 8%. The percentage of treatment effect on time to first opportunistic infection or death is much higher (about 24%).
II. Predicted Survival using PH

The Cox PH model says that $\lambda_i(t, Z) = \lambda_0(t) \exp(\beta Z)$.

What does this imply about the survival function, $S_z(t)$, for the $i$-th individual with covariates $Z_i$?

For the baseline (reference) group, we have:

$$S_0(t) = e^{-\int_0^t \lambda_0(u) du} = e^{-\Lambda_0(t)}$$

This is by definition of a survival function (see intro notes).

For the $i$-th patient with covariates $Z_i$, we have:

$$S_i(t) = e^{-\int_0^t \lambda_i(u) du} = e^{-\Lambda_i(t)}$$

$$= e^{-\int_0^t \lambda_0(u) \exp(\beta Z_i) du}$$

$$= e^{-\exp(\beta Z_i) \int_0^t \lambda_0(u) du}$$

$$= \left[ e^{-\int_0^t \lambda_0(u) du} \right]^{\exp(\beta Z_i)}$$

$$= [S_0(t)]^{\exp(\beta Z_i)}$$

(This uses the mathematical relationship $[e^b]^a = e^{ab}$)
Say we are interested in the survival pattern for single males in the nursing home study. Based on the previous formula, if we had an estimate for the survival function in the reference group, i.e., $\hat{S}_0(t)$, we could get estimates of the survival function for any set of covariates $Z_i$.

**How can we estimate the survival function, $S_0(t)$?**

We could use the KM estimator, but there are a few disadvantages of that approach:

- It would only use the survival times for observations contained in the reference group, and not all the rest of the survival times.

- It would tend to be somewhat choppy, since it would reflect the smaller sample size of the reference group.

- It’s possible that there are no subjects in the dataset who are in the “reference” group (ex. say covariates are age and sex; there is no one of age=0 in our dataset).
Instead, we will use a baseline hazard estimator which takes advantage of the proportional hazards assumption to get a smoother estimate.

\[
\hat{S}_i(t) = [\hat{S}_0(t)]^{\exp(\beta Z_i)}
\]

Using the above formula, we substitute \(\hat{\beta}\) based on fitting the Cox PH model, and calculate \(\hat{S}_0(t)\) by one of the following approaches:

- Breslow estimator (Stata)
- Kalbfleisch/Prentice estimator (SAS)
(1) **Breslow Estimator:**

\[
\hat{S}_0(t) = \exp^{-\hat{\Lambda}_0(t)}
\]

where \(\hat{\Lambda}_0(t)\) is the estimated cumulative baseline hazard:

\[
\hat{\Lambda}(t) = \sum_{j: \tau_j < t} \left( \frac{d_j}{\sum_{k \in R(\tau_j)} \exp(\beta_1 Z_{1k} + \ldots + \beta_p Z_{pk})} \right)
\]

(2) **Kalbfleisch/Prentice Estimator**

\[
\hat{S}_0(t) = \prod_{j: \tau_j < t} \hat{\alpha}_j
\]

where \(\hat{\alpha}_j, j = 1, \ldots, d\) are the MLE’s obtained by assuming that \(S(t; Z)\) satisfies

\[
S(t; Z) = [S_0(t)]e^{\beta Z} = \left[ \prod_{j: \tau_j < t} \alpha_j \right]e^{\beta Z} = \prod_{j: \tau_j < t} \alpha_j e^{\beta Z}
\]
Breslow Estimator: further motivation

The Breslow estimator is based on extending the concept of the Nelson-Aalen estimator to the proportional hazards model.

Recall that for a single sample with no covariates, the Nelson-Aalen Estimator of the cumulative hazard is:

\[ \hat{\Lambda}(t) = \sum_{j: \tau_j < t} \frac{d_j}{r_j} \]

where \( d_j \) and \( r_j \) are the number of deaths and the number at risk, respectively, at the \( j \)-th death time.

When there are covariates and assuming the PH model above, one can generalize this to estimate the cumulative baseline hazard by adjusting the denominator:

\[ \hat{\Lambda}(t) = \sum_{j: \tau_j < t} \left( \frac{d_j}{\sum_{k \in R(\tau_j)} \exp(\beta_1 Z_{1k} + \cdots \beta_p Z_{pk})} \right) \]

Heuristic: The expected number of failures in \( (t, t + \delta t) \) is

\[ d_j \approx \delta t \times \sum_{k \in R(t)} \lambda_0(t) \exp(z_k \hat{\beta}) \]

Hence,

\[ \delta t \times \lambda_0(t_j) \approx \frac{d_j}{\sum_{k \in R(t)} \exp(z_k \hat{\beta})} \]
Kalbfleisch/Prentice Estimator: further motivation

This method is analogous to the Kaplan-Meier Estimator. Consider a discrete time model with hazard \((1 - \alpha_j)\) at the \(j\)-th observed death time.

(Note: we use \(\alpha_j = (1 - \lambda_j)\) to simplify the algebra!)

Thus, for someone with \(z=0\), the survivorship function is

\[
S_0(t) = \prod_{j: \tau_j < t} \alpha_j
\]

and for someone with \(Z \neq 0\), it is:

\[
S(t, Z) = S_0(t)e^{\beta Z} = \left[ \prod_{j: \tau_j < t} \alpha_j \right] e^{\beta Z} = \prod_{j: \tau_j < t} \alpha_j e^{\beta Z}
\]

The likelihood contributions under this model are:

- for someone censored at \(t\): \(S(t, Z)\)
- for someone who fails at \(t_j\):

\[
S(t_{(j-1)}; Z) - S(t_j; Z) = \left[ \prod_{k<j} \alpha_j \right] e^{\beta Z} [1 - \alpha_j e^{\beta Z}]
\]

The solution for \(\alpha_j\) satisfies:

\[
\sum_{k \in D_j} \frac{\exp(Z_k \beta)}{1 - \alpha_j \exp(Z_k \beta)} = \sum_{k \in R_j} \exp(Z_k \beta)
\]

(Note what happens when \(Z = 0\))
Obtaining $\hat{S}_0(t)$ from software packages

- Stata provides the Breslow estimator of $S_0(t; Z)$, but not predicted survivals at specified covariate values..... you have to construct these yourself

- SAS uses the Kalbfleisch/Prentice estimator of the baseline hazard, and can provide estimates of survival at arbitrary values of the covariates with a little bit of programming.

In practice, they are **incredibly** close! (see Fleming and Harrington 1984, *Communications in Statistics*)
Using Stata to Predict Survival

The Stata command `basesurv` calculates the predicted survival values for the reference group, i.e., those subjects with all covariates=0.

(1) **Baseline Survival:**
   To obtain the estimated baseline survival $\hat{S}_0(t)$, follow the example below (for the nursing home data):

   . use nurshome

   . stset los fail

   . stcox married health, basesurv(prsurv)

   . sort los

   . list los prsurv

Stata creates a predicted baseline survival estimate for every observed event time in the dataset, even if there are duplicates.
(2) Predicted Survival for Subgroups

To obtain the estimated survival \( \hat{S}_i(t) \) for any other subgroup (i.e., not the reference or baseline group), follow the Stata commands below:

\[
\begin{align*}
.& \quad \text{predict betaz, xb} \\
.& \quad \text{gen newterm=exp(betaz)} \\
.& \quad \text{gen predsurv=prsurv^newterm} \\
.& \quad \text{sort married health los} \\
.& \quad \text{list married health los predsurv}
\end{align*}
\]

Using SAS to Predict Survival

The SAS command BASELINE calculates the predicted survival values at the event times for a given set of covariate values.

(1) To get the estimated baseline survival $\hat{S}_0(t)$, create a dataset with 0’s for values of all covariates in the model.

(2) To get the estimated survival $\hat{S}_i(t)$ for any other subgroup (i.e., not the reference or baseline group), create a data set which inputs the baseline values of the covariates for the subgroup of interest.

For either case, we then supply the corresponding dataset name to the BASELINE command under PROC PHREG.

By giving the input dataset several lines, each corresponding to a different combination of covariate values, we can compute predicted survival values for more than one group at once.
(1) **Baseline Survival Estimate**

(note that the baseline survival function does not correspond to any observations in our sample, since health status values range from 2-5)

We can get a visual picture of what the proportional hazards assumption implies by looking at these four subgroups.

Nursing home data: Predicted Survival by Subgroup
III. Predicted medians and P-year survival

Predicted Medians
Suppose we want to find the predicted median survival for an individual with a specified combination of covariates (e.g., a single person with health status 5).

Three possible approaches:

(1) Calculate the median from the subset of individuals with the specified covariate combination (using KM approach)

(2) Generate predicted survival curves for each combination of covariates, and obtain the medians directly

</tbody>
</table>

Recall that previously we defined the median as the smallest value of $t$ for which $\hat{S}(t) \leq 0.5$, so the medians from above would be 185, 80, 109, and 48 days for single healthy, single unhealthy, married healthy, and married unhealthy, respectively.
(3) Generate the predicted survival curve from the estimated baseline hazard, as follows:

We want the estimated median \((M)\) for an individual with covariates \(Z_i\). We know

\[
S(M; Z) = [S_0(M)]^{e^{\beta Z_i}} = 0.5
\]

Hence, \(M\) satisfies (multiplying both sides by \(e^{-\beta Z_i}\)):

\[
S_0(M) = [0.5]^{e^{-\beta Z}}
\]

**Ex.** Suppose we want to estimate the median survival for a single unhealthy subject from the nursing home data. The reciprocal of the hazard ratio for unhealthy (health=5) is: \(e^{-0.165*5} = 0.4373\), (where \(\hat{\beta} = 0.165\) for health status)

So, we want \(M\) such that \(S_0(M) = (0.5)^{0.4373} = 0.7385\)

So the median for single unhealthy subject is the 73.8\(^{th}\) percentile of the baseline group.

<table>
<thead>
<tr>
<th>OBS</th>
<th>MARRIED</th>
<th>HEALTH</th>
<th>LOS</th>
<th>PREDSURV</th>
</tr>
</thead>
<tbody>
<tr>
<td>79</td>
<td>0</td>
<td>0</td>
<td>78</td>
<td>0.74028</td>
</tr>
<tr>
<td>80</td>
<td>0</td>
<td>0</td>
<td>80</td>
<td>0.73849</td>
</tr>
<tr>
<td>81</td>
<td>0</td>
<td>0</td>
<td>81</td>
<td>0.73670</td>
</tr>
</tbody>
</table>

So the estimated median would still be 80 days. Note: similar logic can be followed to estimate other quantiles besides the median.
Estimating P-year survival

Suppose we want to find the P-year survival rate for an individual with a specified combination of covariates, $\hat{S}(P; Z_i)$

For an individual with $Z_i = 0$, the P-year survival can be obtained from the baseline survivorship function, $\hat{S}_0(P)$

For individuals with $Z_i \neq 0$, it can be obtained as:

$$\hat{S}(P; Z_i) = [\hat{S}_0(P)]^{\hat{\beta}Z_i}$$

Notes:

- Although I say “P-year” survival, the units of time in a particular dataset may be days, weeks, or months. The answer here will be in the same units of time as the original data.
- If $\hat{\beta}Z_i$ is positive, then the P-year survival rate for the $i$-th individual will be lower than for a baseline individual.

Why is this true?
Model Selection in Survival Analysis

Suppose we have a censored survival time that we want to model as a function of a (possibly large) set of covariates. Two important questions are:

- How to decide which covariates to use
- How to decide if the final model fits well

To address these topics, we’ll consider a new example:

**Survival of Atlantic Halibut - Smith et al**

Hosmer & Lemeshow
Chapter 5: Model Development
Chapter 6: Assessment of Model Adequacy
(sections 6.1-6.2)
Process of Model Selection

Collett (Section 3.6) has an excellent discussion of various approaches for model selection. In practice, model selection proceeds through a combination of

- knowledge of the science
- trial and error, common sense
- automatic variable selection procedures
  - forward selection
  - backward selection
  - stepwise selection

Many advocate the approach of first doing a univariate analysis to “screen” out potentially significant variables for consideration in the multivariate model (see Collett).

Let’s start with this approach.
Univariate KM plots of Atlantic Halibut survival
(continuous variables have been dichotomized)

Which covariates look like they might be important?
Automatic Variable selection procedures in Stata and SAS

**Statistical Software:**
- Stata: `sw` command before `cox` command
- SAS: `selection=` option on model statement of `proc phreg`

**Options:**
1. forward
2. backward
3. stepwise
4. best subset (SAS only, using `score` option)

One drawback of these options is that they can only handle variables one at a time. When might that be a disadvantage?
Collett’s Model Selection Approach  
Section 3.6.1

This approach assumes that all variables are considered to be on an equal footing, and there is no a priori reason to include any specific variables (like treatment).

**Approach:**

1. Fit a univariate model for each covariate, and identify the predictors significant at some level $p_1$, say 0.20.

2. Fit a multivariate model with all significant univariate predictors, and use *backward* selection to eliminate non-significant variables at some level $p_2$, say 0.10.

3. Starting with final step (2) model, consider each of the non-significant variables from step (1) using *forward* selection, with significance level $p_3$, say 0.10.

4. Do final pruning of main-effects model (omit variables that are non-significant, add any that are significant), using *stepwise* regression with significance level $p_4$. At this stage, you may also consider adding interactions between any of the main effects currently in the model, under the hierarchical principle.

Collett recommends using a likelihood ratio test for all variable inclusion/exclusion decisions.
Stata Command for Forward Selection:

**Forward Selection** $\Rightarrow$ use *pe($\alpha$)* option, where $\alpha$ is the significance level for entering a variable into the model.

```
. use halibut
. stset survtime censor
. sw cox survtime towdur depth length handling logcatch, > dead(censor) pe(.05)
```

```
begin with empty model

p = 0.0000 < 0.0500 adding handling
p = 0.0000 < 0.0500 adding logcatch
p = 0.0010 < 0.0500 adding towdur
p = 0.0003 < 0.0500 adding length

Cox Regression -- entry time 0
Number of obs = 294
chi2(4) = 84.14
Prob > chi2 = 0.0000
Log Likelihood = -1257.6548 Pseudo R2 = 0.0324

| survtime    | censor | Coef.  | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|-------------|--------|--------|-----------|--------|-------|----------------------|
| handling    | .0548994 | .0098804 | 5.556 | 0.000 | .0355341 | .0742647 |
| logcatch    | -.1846548 | .051015  | -3.620 | 0.000 | .2846423 | -.0846674 |
| towdur      | .5417745 | .1414018 | 3.831 | 0.000 | .2646321 | .818917   |
| length      | -.0366503 | .0100321 | -3.653 | 0.000 | -.0563129 | -.0169877 |
```
Stata Command for Backward Selection:

**Backward Selection** \(\implies\) use \(pr(\alpha)\) option, where \(\alpha\) is the significance level for a variable to remain in the model.

```
. sw cox survtime towdur depth length handling logcatch, 
   > dead(censor) pr(.05)
```

begin with full model

\(p = 0.1991 >= 0.0500\) removing depth

- Cox Regression -- entry time 0

| survtime | Coef. | Std. Err. | z   | P>|z|  | [95% Conf. Interval] |
|----------|-------|-----------|-----|------|----------------------|
| censor   |       |           |     |      |                      |

Number of obs = 294

chi2(4) = 84.14

Prob > chi2 = 0.0000

Log Likelihood = -1257.6548

Pseudo R2 = 0.0324
Stata Command for Stepwise Selection:

**Stepwise Selection**  \implies  use both \textit{pe}(.) and \textit{pr}(.) options, with \textit{pr}(.) > \textit{pe}(.)

```stata
. sw cox survtime towdur depth length handling logcatch, > dead(censor) pr(0.10) pe(0.05)
```

begin with full model

\[ p = 0.1991 \geq 0.1000 \text{ removing depth} \]

Cox Regression -- entry time 0

\begin{align*}
\text{Number of obs} & = 294 \\
\text{chi2(4)} & = 84.14 \\
\text{Prob > chi2} & = 0.0000 \\
\text{Log Likelihood} & = -1257.6548 \\
\text{Pseudo R2} & = 0.0324 \\
\end{align*}

| survivor | Coef. | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|---------|-------|-----------|-----|------|----------------------|
| towdur  | .5417745 | .1414018  | 3.831 | 0.000 | .2646321, .818917    |
| handling | .0548994 | .0098804  | 5.556 | 0.000 | .0355341, .0742647   |
| length  | -.0366503 | .0100321  | -3.653 | 0.000 | -.0563129, -.0169877 |
| logcatch | -.1846548 | .051015  | -3.620 | 0.000 | -.2846423, -.0846674 |

It is also possible to do forward stepwise regression by including both \textit{pr}(.) and \textit{pe}(.) options with \texttt{forward} option

Notes:

- When the halibut data was analyzed with the forward, backward and stepwise options, the same final model was reached. However, this will not always be the case.

- Variables can be forced into the model using the **lockterm** option in Stata and the **include** option in SAS. Any variables that you want to force inclusion of must be listed first in your model statement.

- Stata uses the Wald test for both forward and backward selection, although it has an option to use the likelihood ratio test instead (**lrtest**). SAS uses the score test to decide what variables to add and the Wald test for what variables to remove.

- If you fit a range of models manually, you can apply the AIC criteria described by Collett:

  \[
  \text{minimize } \text{AIC} = -2 \log(\hat{L}) + (\alpha \times q)
  \]

  where \( q \) is the number of unknown parameters in the model and \( \alpha \) is typically between 2 and 6 (they suggest \( \alpha = 3 \)).

  The model is then chosen which minimizes the AIC (similar to maximizing log-likelihood, but with a penalty for number of variables in the model)
Questions:

• When might we want to force certain variables into the model?
  
  (1) to examine interactions
  (2) to keep main effects in the model
  (3) to calculate a score test for a particular effect

• Would it be possible to get different final models from SAS and Stata?

• Based on what we’ve seen in the behavior of Wald tests, would SAS or Stata be more likely to add a covariate to a model in a forward selection model?

• If we use the AIC criteria with $\alpha = 3$, how does that compare to the likelihood ratio test?
Assessing overall model fit

How do we know if the model fits well?

- Always look at univariate plots (Kaplan-Meiers)

Construct a Kaplan-Meier survival plot for each of the important predictors, like the ones shown at the beginning of these notes.

- Check proportionality assumption (this will be the topic of the next lecture)

- **Check residuals!**
  
  (a) generalized (Cox-Snell)
  
  (b) martingale
  
  (c) deviance
  
  (d) Schoenfeld
  
  (e) weighted Schoenfeld
Residuals for survival data are slightly different than for other types of models, due to the censoring. Before we start talking about residuals, we need an important basic result:

**Inverse CDF:**

If $T_i$ (the survival time for the $i$-th individual) has survivorship function $S_i(t)$, then the transformed random variable $S_i(T_i)$ (i.e., the survival function evaluated at the actual survival time $T_i$) should be from a uniform distribution on $[0, 1]$, and hence $-\log[S_i(T_i)]$ should be from a unit exponential distribution.

More mathematically:

If $T_i \sim S_i(t)$

then $S_i(T_i) \sim Uniform[0, 1]$

and $-\log S_i(T_i) \sim Exponential(1)$
(a) Generalized (Cox-Snell) Residuals:

The implication of the last result is that if the model is correct, the estimated cumulative hazard for each individual at the time of their death or censoring should be like a censored sample from a unit exponential. This quantity is called the generalized or Cox-Snell residual.

Here is how the generalized residual might be used. Suppose we fit a PH model:

\[ S(t; Z) = [S_0(t)]^{\exp(\beta Z)} \]

or, in terms of hazards:

\[
\lambda(t; Z) = \lambda_0(t) \exp(\beta Z) \\
= \lambda_0(t) \exp(\beta_1 Z_1 + \beta_2 Z_2 + \cdots + \beta_k Z_k)
\]

After fitting, we have:

- \( \hat{\beta}_1, \ldots, \hat{\beta}_k \)
- \( \hat{S}_0(t) \)
So, for each person with covariates $Z_i$, we can get

$$\hat{S}(t; Z_i) = [\hat{S}_0(t)]^{\exp(\beta Z_i)}$$

This gives a predicted survival probability at each time $t$ in the dataset (see notes from the previous lecture).

Then we can calculate

$$\hat{\Lambda}_i = -\log[\hat{S}(T_i; Z_i)]$$

In other words, first we find the predicted survival probability at the actual survival time for an individual, then log-transform it.
Example: Nursing home data

Say we have

- a single male
- with actual duration of stay of 941 days ($X_i = 941$)

We compute the entire distribution of survival probabilities for single males, and obtain $\hat{S}(941) = 0.260$.

$$- \log[\hat{S}(941, \text{single male})] = - \log(0.260) = 1.347$$

We repeat this for everyone in our dataset. These should be like a censored sample from an exponential (1) distribution if the model fits the data well.

Based on the properties of a unit exponential model

- plotting $- \log(\hat{S}(t))$ vs $t$ should yield a straight line
- plotting $\log[- \log S(t)]$ vs $\log(t)$ should yield a straight line through the origin with slope=1.

To convince yourself of this, start with $S(t) = e^{-\lambda t}$ and calculate $\log[- \log S(t)]$. What do you get for the slope and intercept?

(Note: this does not necessarily mean that the underlying distribution of the original survival times is exponential!)
Obtaining the generalized residuals from Stata

- Fit a Cox PH model with the `stcox` command, along with the `mgale(newvar)` option
- Use the `predict` command with the `csnell` option
- Define a survival dataset using the Cox-Snell residuals as the “pseudo” failure times
- Calculate the estimated KM survival
- Take the $\log[-\log(S(t))]$ based on the above
- Generate the log of the Cox-Snell residuals
- Graph $\log[-\log S(t)]$ vs $\log(t)$

```
. stcox towdur handling length logcatch, mcale(mg)
. predict csres, csnell
. stset csres censor
. sts list
. sts gen survcs=s
. gen lls=log(-log(survcs))
. gen loggenr=log(csres)
. graph lls loggenr
```
Allison states “Cox-Snell residuals... are not very informative for Cox models estimated by partial likelihood.” He instead prefers deviance residuals (later).
Obtaining the generalized residuals from SAS

The **generalized residuals** can be obtained from SAS after fitting a PH model using the `output` statement with the `logsurv` option.

```sas
proc phreg data=fish;
   model survtime*censor(0) = towdur handling logcatch length;
   output out=phres logsurv=genres;

*** take negative log Pr(survival) at each persons survtime;
data phres;
   set phres;
   genres=-genres;

*** Now we treat the generalized residuals as the input dataset;
*** to evaluate whether the assumption of an exponential;
*** distribution is appropriate;
proc lifetest data=phres outsurv=survres;
   time genres*censor(0);

data survres;
   set survres;
   lls=log(-log(survival));
   loggenr=log(genres);

proc gplot data=survres;
   plot lls*loggenr;
run;
```
(b) Martingale Residuals
(see Fleming and Harrington, p.164)

Martingale residuals are defined for the $i$-th individual as:

$$r_i = \delta_i - \hat{\Lambda}(T_i)$$

Properties:

- $r_i$’s have mean 0
- range of $r_i$’s is between $-\infty$ and 1
- approximately uncorrelated (in large samples)

Interpretation: the residual $r_i$ can be viewed as the difference between the observed number of deaths (0 or 1) for subject $i$ between time 0 and $T_i$, and the expected numbers based on the fitted model.
The **martingale residuals** can be obtained from Stata using the `mgale` option shown previously.

Once the martingale residual is created, you can plot it versus the predicted log HR (i.e., $\beta Z_i$), or any of the individual covariates.

```
. stcox towdur handling length logcatch, mgle(mg)
. predict betaz=xb
. graph mg betaz
. graph mg logcatch
. graph mg towdur
. graph mg handling
. graph mg length
```
The *martingale residuals* can be obtained from SAS after fitting a PH model using the `output` statement with the `resmart` option.

Once you have them, you can

- plot against predicted values
- plot against covariates

```sas
proc phreg data=fish;
    model survtime*censor(0) = towdur handling logcatch length;
    output out=phres resmart=mres xbeta=xb;
run;
```

```sas
proc gplot data=phres;
    plot mres*xb; /* predicted values */
    plot mres*towdur;
    plot mres*handling;
    plot mres*logcatch;
    plot mres*length;
run;
```

Allison still prefers the deviance residuals (next)

267
(c) Deviance Residuals

One problem with the martingale residuals is that they tend to be asymmetric.

A solution is to use **deviance residuals**. For person $i$, these are defined as a function of the martingale residuals ($r_i$):

$$\hat{D}_i = \text{sign}(\hat{r}_i)\sqrt{-2[\hat{r}_i + \delta_i \log(\delta_i - \hat{r}_i)]}$$

In Stata, the deviance residuals are generated using the same approach as the Cox-Snell residuals.

```stata
   . stcox towdur handling length logcatch, mgale(mg)
   . predict devres, deviance
```

and then they can be plotted versus the predicted log(HR) or the individual covariates, as shown for the Martingale residuals.

In SAS, just use **resdev** option instead of **resmart**.

Deviance residuals behave much like residuals from OLS regression (i.e., mean=0, s.d.=1). They are negative for observations with survival times that are smaller than expected.

(d) Schoenfeld Residuals

These are defined at each observed failure time as:

\[ r_{ij}^s = Z_{ij}(t_i) - \bar{Z}_j(t_i) \]

Notes:
- represent the difference between the observed covariate and the average over the risk set at that time
- calculated for each covariate
- not defined for censored failure times.
- useful for assessing time trend or lack or proportionality, based on plotting versus event time
- sum to zero, have expected value zero, and are uncorrelated (in large samples)

In Stata, the Schoenfeld residuals are generated in the `stcox` command itself, using the `schoenf(newvar(s))` option:

```
. stcox towdur handling length logcatch, schoenf(towres handres lenres logres)
```

```
. graph towres survtime
```

In SAS, add to the output line

`RESSCH=name1 name2 ... namek`

for up to \( k \) regressors in the model.
Schoenfeld Residuals

Schoenfeld resids for towing vs survival time

Schoenfeld resids for length vs survival time

Schoenfeld resids for log(catch) vs survival time

Schoenfeld resids for handling vs survival time
(e) Weighted Schoenfeld Residuals

These are actually used more often than the previous un-weighted version, because they are more like the typical OLS residuals (i.e., symmetric around 0).

They are defined as:

$$r_{ij}^w = n\hat{V} r_{ij}^s$$

where $\hat{V}$ is the estimated variance of $\hat{\beta}$. The weighted residuals can be used in the same way as the unweighted ones to assess time trends and lack of proportionality.

In Stata, use the command:

```
. stcox towdur length logcatch handling depth, scaledsch(towres2 > lenres2 logres2 handres2 depres2)
. graph logres2 survtime
```

In SAS, add to the output line

```
WTRESSCH=name1 name2 ... namek
```

for up to $k$ regressors in the model.
Weighted Schoenfeld Residuals

Weighted Schoenfeld residuals for towing vs time

Schoenfeld residuals for length vs time

Schoenfeld residuals for log(catch) vs time

Schoenfeld residuals for handling vs time
Using Residual plots to explore relationships

If you calculate martingale or deviance residuals without any covariates in the model and then plot against covariates, you obtain a graphical impression of the relationship between the covariate and the hazard.

In Splus, it is easy to do this (also possible in stata using the “estimate” option)

```r
** read in the dataset and fit a cox PH model
fish_read.table('fish.data',header=T)
x_fish$towdur
fishres_coxreg(fish$time, fish$censor, x, resid="martingale",iter.max=0)

** the 2 commands below set up the postscript file, with 4 graphs
postscript("fishres.plt",horizontal=F,height=10,width=7)
par(mfrow=c(2,2),oma=c(0,0,2,0))

** plot the martingale residuals vs each of the other covariates
** and add a lowess smoothed fit to the plot
plot(fish$depth, fishres$resid, xlab="depth")
lines(lowess(fish$depth,fishres$resid,iter=0))
plot(fish$length, fishres$resid, xlab="length")
lines(lowess(fish$length,fishres$resid,iter=0))
plot(fish$handling, fishres$resid, xlab="handling")
lines(lowess(fish$handling,fishres$resid,iter=0))
plot(fish$logcatch, fishres$resid, xlab="logcatch")
lines(lowess(fish$logcatch,fishres$resid,iter=0))
```
Splus Plots of Martingale Residuals for Cox Model containing only towing duration as a predictor, vs other covariates.
(f) Deletion diagnostics

Deletion diagnostics are defined generally as:

\[ \delta_i = \hat{\beta} - \hat{\beta}(i) \]

In other words, they are the difference between the estimated regression coefficient using all observations and that without the \( i \)-th individual. This can be useful for assessing the influence of an individual.

In SAS PROC PHREG, we use the dfbeta option:
(Note that there is a separate dfbeta calculated for each of the predictors.)

```
proc phreg data=fish;
   model survtime*censor(0)=towdur handling logcatch length;
   id id;
   output out=phinfl dfbeta=dtow dhand dlogc dlength ld=lrchange;
proc univariate data=phinfl;
   var dtow dhand dlogc dlength lrchange;
   id id;
run;
```

The proc univariate procedure will supply the 5 smallest values and the 5 largest values. The \textbf{`id`} statement means that these will be labeled with the value of id from the dataset.
Other Influence diagnostics:
The **LD** option is another method for checking influence. It calculates how much the log-likelihood ($x^2$) would change if the $i$-th person was removed from the sample.

\[
LD_i = 2 \left[ \log L(\hat{\beta}) - \log L(\hat{\beta}_{-i}) \right]
\]

- $\hat{\beta}$ = MLE for all parameters with everyone included
- $\hat{\beta}_{-i}$ = MLE with $i$-th subject omitted

Again, the proc univariate procedure in SAS will identify the observations with the largest and smallest values of the **lrchange** diagnostic measure.
Can we improve the model?

The plots appear to have some structure, which indicate that we could be leaving something out. It is always a good idea to check for interactions:

In this case, there are several important interactions. I used a backward selection model forcing all main effects to be included, and considering all pairwise interactions. Here are the results:

</tbody>
</table>

**Interpretation:**
Handling alone doesn’t seem to affect survival, unless it is combined with a longer towing duration or shallower trawling depths.
An alternative modeling strategy when we have fewer covariates

With a dataset with only 5 main effects, it would make sense to consider interactions from the start. How many would there be?

- Fit model with all main effects and pairwise interactions

- Then use backward selection to eliminate non-significant pairwise interactions (remember to force the main effects into the model at this stage)

- Once non-significant pairwise interactions have been eliminated, you could consider backwards selection to eliminate any non-significant main effects that are not involved in remaining interaction terms

- After obtaining final model, use residuals to check fit of model.
Assessing the PH Assumption

So far, we’ve been considering the following Cox PH model:

\[
\lambda(t, Z) = \lambda_0(t) \exp(\beta Z) = \lambda_0(t) \exp(\sum \beta_j Z_j)
\]

where \(\beta_j\) is the parameter for the \(j\)-th covariate \((Z_j)\).

Important features of this model:

(1) the baseline hazard depends on \(t\), but not on the covariates \(Z_1, ..., Z_p\)

(2) the hazard ratio, i.e., \(\exp(\beta Z)\), depends on the covariates \(Z = (Z_1, ..., Z_p)\), but not on time \(t\).

Assumption (2) is what led us to call this a proportional hazards model. That’s because we could take the ratio of the hazards for two individuals with covariates \(Z_i\) and \(Z_{i'}\), and write it as a constant in terms of the covariates.
Proportional Hazards Assumption

Hazard Ratio:

\[
\frac{\lambda(t, Z_i)}{\lambda(t, Z_{i'})} = \frac{\lambda_0(t) \exp(\beta Z_i)}{\lambda_0(t) \exp(\beta Z_{i'})}
= \frac{\exp(\beta Z_i)}{\exp(\beta Z_{i'})}
= \exp[\beta(Z_i - Z_{i'})]
= \exp[\sum \beta_j (Z_{ij} - Z_{i'j})] = \theta
\]

In the last formula, \( Z_{ij} \) is the value of the \( j \)-th covariate for the \( i \)-th individual. For example, \( Z_{42} \) might be the value of GENDER (0 or 1) for the 4-th person.

We can also write the hazard for the \( i \)-th person as a constant times the hazard for the \( i' \)-th person:

\[
\lambda(t, Z_i) = \theta \lambda(t, Z_{i'})
\]

Thus, the HR between two types of individuals is constant (i.e., \( =\theta \)) over time. These are mathematical ways of stating the proportional hazards assumption.
There are several options for checking the assumption of proportional hazards:

I. **Graphical**
   
   (a) Plots of survival estimates for two subgroups
   (b) Plots of $\log[- \log(\hat{S})]$ vs $\log(t)$ for two subgroups
   (c) Plots of weighted Schoenfeld residuals vs time
   (d) Plots of observed survival probabilities versus expected under PH model (see Kleinbaum, ch.4)

II. **Use of goodness of fit tests** - we can construct a goodness-of-fit test based on comparing the observed survival probability (from **sts list**) with the expected (from **stcox**) under the assumption of proportional hazards - see Kleinbaum ch.4

III. **Including interaction terms between a covariate and $t$** (time-dependent covariates)
How do we interpret the above?

Kleinbaum (and other texts) suggest a strategy of assuming that PH holds unless there is very strong evidence to counter this assumption:

- estimated survival curves are fairly separated, then cross
- estimated log cumulative hazard curves cross, or look very unparallel over time
- weighted Schoenfeld residuals clearly increase or decrease over time (you could fit a OLS regression line and see if the slope is significant)
- test for time × covariate interaction term is significant (this relates to time-dependent covariates)

If PH doesn’t exactly hold for a particular covariate but we fit the PH model anyway, then what we are getting is sort of an average HR, averaged over the event times.

In most cases, this is not such a bad estimate. Allison claims that too much emphasis is put on testing the PH assumption, and not enough to other important aspects of the model.
**Implications of proportional hazards**

Consider a PH model with a single covariate, $Z$:

$$\lambda(t; Z) = \lambda_0(t)e^{\beta Z}$$

What does this imply for the relation between the survivorship functions at various values of $Z$?

Under PH,

$$\log[-\log[S(t; Z)]] = \log[-\log[S_0(t)]] + \beta Z$$

In general, we have the following relationship:

$$\Lambda_i(t) = \int_0^t \lambda_i(u)du$$

$$= \int_0^t \lambda_0(u)\exp(\beta Z_i)du$$

$$= \exp(\beta Z_i) \int_0^t \lambda_0(u)du$$

$$= \exp(\beta Z_i) \Lambda_0(t)$$

This means that the ratio of the cumulative hazards is the same as the ratio of hazard rates:

$$\frac{\Lambda_i(t)}{\Lambda_0(t)} = \exp(\beta Z_i) = \exp(\beta_1 Z_{1i} + \cdots + \beta_p Z_{pi})$$
Using the above relationship, we can show that:

\[
\beta Z_i = \log \left( \frac{\Lambda_i(t)}{\Lambda_0(t)} \right) \\
= \log \Lambda_i(t) - \log \Lambda_0(t) \\
= \log[-\log S_i(t)] - \log[-\log S_0(t)]
\]

so \( \log[-\log S_i(t)] = \log[-\log S_0(t)] + \beta Z_i \)

Thus, to assess if the hazards are actually proportional to each other over time (using graphical option I(b))

- calculate Kaplan Meier Curves for various levels of \( Z \)
- compute \( \log[-\log(\hat{S}(t; Z))] \) (i.e., log cumulative hazard)
- plot vs log-time to see if they are parallel (lines or curves)

Note: If \( Z \) is continuous, break into categories.
Question: Why not just compare the underlying hazard rates to see if they are proportional?

Here’s two simulated examples with hazards which are truly proportional between the two groups:

**Weibull-type hazard:**

![Weibull-type hazard plot]

**U-shaped hazard:**

![U-shaped hazard plot]

Reason 1: It’s hard to eyeball these figures and see that the hazard rates are proportional - it would be easier to look for a constant shift between lines.
Reason 2: Estimated hazard rates tend to be more unstable than the cumulative hazard rate

Consider the nursing home example (where we think PH is reasonable). If we group the data into intervals and calculate the hazard rate using actuarial method, we get these plots:

200 day intervals:  
100 day intervals:  
50 day intervals:  
25 day intervals:
In contrast, the log cumulative hazard plots are easier to interpret and tend to give more stable estimates.

Ex: Nursing Home - gender and marital status

```plaintext
proc lifetest data=pop outsurv=survres;
  time los*fail(0);
  strata gender;
  format gender sexfmt.;
  title 'Duration of Length of Stay in nursing homes';

data survres;
  set survres;
  label log_los='Log(Length of stay in days)';
  if los > 0 then log_los=log(los);
  if survival<1 then lls=log(-log(survival));

proc gplot data=survres;
  plot lls*log_los=gender;
  format gender sexfmt.;
  title2 'Plots of log-log KM versus log-time';
run;
```

The statements for marital status are similar, substituting MARRIED for GENDER.

Note: This is equivalent to comparing plots of the log cumulative hazard, log(\(\hat{\Lambda}(t)\)), between the covariate levels, since

\[
\Lambda(t) = \int_0^t \lambda(u; Z)du = -\log[S(t)]
\]
Assessment of proportional hazards for gender and marital status in nursing home data (Morris)

Duration of Length of Stay in nursing homes
Plots of log-log KM versus log-time

Duration of Length of Stay in nursing homes
Plots of log-log KM versus log-time
Assessing proportionality with several covariates

If there is enough data and you only have a couple of covariates, create a new covariate that takes a different value for every combination of covariate values.

**Example:** Health status and gender for nursing home

data pop;
    infile 'ch12.dat';
    input los age rx gender married health fail;
    if gender=0 and health=2 then hlthsex=1;
    if gender=1 and health=2 then hlthsex=2;
    if gender=0 and health=5 then hlthsex=3;
    if gender=1 and health=5 then hlthsex=4;

proc format;
    value hsfmt
    1='Healthier Women'
    2='Healthier Men'
    3='Sicker Women'
    4='Sicker Men';

proc lifetest data=pop outsurv=survres;
    time los*fail(0);
    strata hlthsex;
    format hlthsex hsfmt.;
    title 'Length of Stay in nursing homes';

data survres;
    set survres;
    label log_los='Log(Length of stay in days)';
    label hlthsex='Health/Gender Status';
    if los > 0 then log_los=log(los);
    if survival<1 lls=log(-log(survival));

proc gplot data=survres;
    plot lls*log_los=hlthsex;
    format hlthsex hsfmt.;
    title2 'Plots of log-log KM versus log-time';
run;
Log[-log(survival)] Plots for Health status*gender

Length of Stay in nursing homes

Plots of log-log KM versus log-time

If there are too many covariates (or not enough data) for this, then there is a way to test proportionality for each variable, one at a time, using the stratification option.
What if proportional hazards fails?

- do a stratified analysis

- include a time-varying covariate to allow changing hazard ratios over time

- include interactions with time

The second two options relate to time-dependent covariates, which will be covered in future lectures.

We will focus on the first alternative, and then the second two options will be briefly described.
Stratified Analyses

Suppose:

- we are happy with the proportionality assumption on $Z_1$
- proportionality simply does not hold between various levels of a second variable $Z_2$.

If $Z_2$ is discrete (with $a$ levels) and there is enough data, fit the following 
stratified model:

$$\lambda(t; Z_1, Z_2) = \lambda_{Z_2}(t)e^{\beta Z_1}$$

For example, a new treatment might lead to a 50% decrease in hazard of death versus the standard treatment, but the hazard for standard treatment might be different for each hospital.

A stratified model can be useful both for primary analysis and for checking the PH assumption.
Assessing PH Assumption for Several Covariates

Suppose we have several covariates ($Z = Z_1, Z_2, \ldots, Z_p$), and we want to know if the following PH model holds:

$$\lambda(t; Z) = \lambda_0(t) \ e^{\beta_1 Z_1 + \ldots + \beta_p Z_p}$$

To start, we fit a model which stratifies by $Z_k$:

$$\lambda(t; Z) = \lambda_{0Z_k}(t) \ e^{\beta_1 Z_1 + \ldots + \beta_{k-1} Z_{k-1} + \beta_{k+1} Z_{k+1} + \ldots + \beta_p Z_p}$$

Since we can estimate the survival function for any subgroup, we can use this to estimate the baseline survival function, $S_{0Z_k}(t)$, for each level of $Z_k$.

Then we compute $-\log S(t)$ for each level of $Z_k$, controlling for the other covariates in the model, and graphically check whether the log cumulative hazards are parallel across strata levels.
Ex: PH assumption for gender (nursing home data):

- include married and health as covariates in a Cox PH model, but stratify by gender.
- calculate the baseline survival function for each level of the variable gender (i.e., males and females)
- plot the log-cumulative hazards for males and females and evaluate whether the lines (curves) are parallel

In the above example, we make the PH assumption for married and health, but not for gender.

This is like getting a KM survival estimate for each gender without assuming PH, but is more flexible since we can control for other covariates.

We would repeat the stratification for each variable for which we wanted to check the PH assumption.
SAS Code for Assessing PH within Stratified Model:

```
data pop;
  infile 'ch12.dat';
  input los age rx gender married health fail;
  if los<=0 then delete;

data inrisks;
  input married health;
cards;
0 2
;

proc format;
  value sexfmt
    i='Male'
    0='Female';

proc phreg data=pop;
  model los*fail(0)=married health;
  strata gender;
  baseline covariates=inrisks out=outph
    loglogs=lls / nomean;

proc print data=outph;
  title 'Log Cumulative Hazard Estimates by Gender';
  title2 'Controlling for Marital and Health Status';

data outph;
  set outph;
  if los>0 then log_los=log(los);
  label log_los='Log(LOS)'
    lls='Log Cumulative Hazard';

proc gplot data=outph;
  plot lls*log_los=gender;
  format gender sexfmt.;
  title1 'Log-log Survival versus log-time by Gender';
run;
```
Log[-log(survival)] Plots for Gender
Controlling for Marital and Health Status

Log–log Survival versus log–time by Gender
Models with Time-dependent Interactions

Consider a PH model with two covariates $Z_1$ and $Z_2$. The standard PH model assumes

$$
\lambda(t; Z) = \lambda_0(t) \ e^{\beta_1 Z_1 + \beta_2 Z_2}
$$

However, if the log-hazards are not really parallel between the groups defined by $Z_2$, then you can try adding an interaction with time:

$$
\lambda(t; Z) = \lambda_0(t) \ e^{\beta_1 Z_1 + \beta_2 Z_2 + \beta_3 Z_2 t}
$$

A test of the coefficient $\beta_3$ would be a test of the proportional hazards assumption for $Z_2$.

If $\beta_3$ is positive, then the hazard ratio would be increasing over time; if negative, then decreasing over time.

Changes in covariate status sometimes occur naturally during a study (ex. patient gets a kidney transplant), and are handled by introducing time-dependent covariates.
Using **Stata** to Assess Proportional Hazards

Stata has two commands which can be used to graphically assess the proportional hazards assumption, using graphical options (b) and (d) described previously:

- **stphplot**: plots \(-\log[-\log(-(S(t)))]\) curves for each category of a nominal or ordinal independent variable versus log(time). Optionally, these estimates can be adjusted for other covariates.

- **stcoxkm**: plots Kaplan-Meier observed survival curves and compares them to the Cox predicted curves for the same variable. (No need to run stcox prior to this command, it will be done automatically)

For either command, you must have **stset** your data first.

You must specify **by()** with **stcoxkm** and you must specify either **by()** or **strata()** with **stphplot**.
Assessing PH Assumption for a Single Covariate by Comparing \( - \log[- \log(S(t))] \) Curves

```plaintext
. use nurshome
. stset los fail
. stphplot, by(gender)
```

Note that the lines will be going from top left to bottom right, rather than bottom left to top right, since we are plotting \( - \log[- \log(S(t))] \) rather than \( - \log[- \log(S(t))] \).

This will give a plot similar to that on p.10 (top).

Of course, you’ll want to make your plot prettier by adding titles and labels, as follows:

```plaintext
. stphplot, by(gender) xlab ylab b2(log(Length of Stay))
>title(Evaluation of PH Assumption) saving(phplot)
```
Assessing PH Assumption for Several Covariates by Comparing $-\log[-\log(S(t))]$ Curves

. use nurshome
. stset los fail
. gen hlthsex=1
. replace hlthsex=2 if health==2 & gender==1
. replace hlthsex=3 if health==5 & gender==0
. replace hlthsex=4 if health==5 & gender==1
. tab hlthsex
. stphplot, by(hlthsex)

This will give a plot similar to that on p.12.
Assessing PH Assumption for a Single Covariate Controlling for the Levels of Other Covariates

. use nurshome

. stset los fail

. stphplot, strata(gender) adjust(married health)

This will produce a plot similar to that on p.18.
Assessing PH Assumption for a Covariate
By Comparing Cox PH Survival to KM Survival

To construct plots based on option I(d), use the `stcoxkm` command, either for a single covariate or for a newly generated covariate (like `hlthsex`) which represents combined levels of more than one covariate.

```
. use nurshome
. stset los fail
. stcoxkm, by(gender)
. stcoxkm, by(hlthsex)
```

As usual, you’ll want to add titles, labels, and save your graph for later use.
So far, we’ve been considering the following Cox PH model:

\[
\lambda(t, Z) = \lambda_0(t) \exp(\beta Z) \\
= \lambda_0(t) \exp(\sum \beta_j Z_j)
\]

where \( \beta_j \) is the parameter for the \( j \)-th covariate \( (Z_j) \).

**Important features of this model:**

(1) the baseline hazard depends on \( t \), but not on the covariates \( Z_1, \ldots, Z_p \)

(2) the hazard ratio \( \exp(\beta Z) \) depends on the covariates \( Z_1, \ldots, Z_p \), but not on time \( t \).

Now we want to relax the second assumption, and allow the hazard ratio to depend on time \( t \).
Example to motivate time-dependent covariates

Stanford Heart transplant example:

**Variables:**
- **SURVIVAL** - time from program enrollment until death or censoring
- **DEAD** - indicator of death (1) or censoring (0)
- **TRANSPL** - whether patient ever had transplant (1 if yes, 2 if no)
- **SURGERY** - previous heart surgery prior to program
- **AGE** - age at time of acceptance into program
- **WAIT** - time from acceptance into program until transplant surgery (= . for those without transplant)

Initially, a Cox PH model was fit for predicting survival time:

\[
\lambda(t, Z) = \lambda_0(t) \exp(\beta_1 \cdot \text{transpl} + \beta_2 \cdot \text{surgery} + \beta_3 \cdot \text{age})
\]

However, this model could give misleading results, since patients who died more quickly had less time available to get transplants. A model with a time dependent indicator of whether a patient had a transplant at each point in time might be more appropriate:

\[
\lambda(t, Z) = \lambda_0(t) \exp(\beta_1 \cdot \text{trnstime} + \beta_2 \cdot \text{surgery} + \beta_3 \cdot \text{age})
\]

where TRNSTIME = 1 if TRANSPL=1 and WAIT> t
SAS code for these two models

Time-independent covariate for TRANSPL:

```sas
proc phreg data=stanford;
  model survival*dead(0)=transpl surgery age;
run;
```

Time-dependent covariate for TRANSPL:

```sas
proc phreg data=stanford;
  model survival*dead(0)=trnstime surgery age;
  if wait>survival or wait=. then trnstime=0;
    else trnstime=1;
run;
```
If we add time-dependent covariates or interactions with time to the Cox proportional hazards model, then it is not “proportional hazards” model any longer.

We refer to it as an “extended Cox model”.

Comparison with a single binary predictor (like heart transplant):

- A standard Cox PH model would compare the survival distributions between those without a transplant (ever) to those with a transplant. A subject’s transplant status at the end of the study would determine which category they were put into for the entire study follow-up.

- An extended Cox model would compare the risk of an event between transplant and non-transplant at each event time, but would re-evaluate which risk group each person belonged in based on whether they’d had a transplant by that time.
Recidivism Example: (see Allison, p.42)

Recidivism study:
432 male inmates were followed for one year after release from prison, to evaluate risk of re-arrest as function of financial aid (FIN), age at release (AGE), race (RACE), full-time work experience prior to first arrest (WEXP), marital status (MAR), parole status (PARO=1 if released with parole, 0 otherwise), and number of prior convictions (PRIO). Data were also collected on employment status over time during the year.

Time-independent model:
A time independent model might include the employment status of the individual at the beginning of the study (1 if employed, 0 if unemployed), or perhaps at any point during the year.

Time-dependent model:
However, employment status changes over time, and it may be the more recent employment status that would affect the hazard for re-arrest. For example, we might want to define a time-dependent covariate for each month of the study that indicates whether the individual was employed during the past month.
Extended Cox Model

**Framework:**
For individual $i$, suppose we have their failure time, failure indicator, and a summary of their covariate values over time:

$$(X_i, \delta_i, \{Z_i(t), t \in [0, X_i]\}),$$

$\{Z_i(t), t \in [0, X_i]\}$ represents the **covariate path** for the $i$-th individual while they are in the study, and the covariates can take different values at different times.

**Assumptions:**
- conditional on an individual’s covariate history, the hazard for failure at time $t$ depends only on the value of the covariates at that time:

$$\lambda(t; \{Z_i(u), u \in [0, t]\}) = \lambda(t; Z_i(t))$$

- the Cox model for the hazard holds:

$$\lambda(t; Z_i(t)) = \lambda_0(t) e^{\beta Z_i(t)}$$

**Survivor function:**

$$S(t; Z) = \exp\{- \int_0^t \exp(\beta Z(u)) \lambda_0(u)du\}$$

and depends on the values of the time dependent variables over the interval from 0 to $t$.

This is the classic formulation of the time varying Cox regression survival model.
Kinds of time-varying covariates:

- **internal covariates:**
  variables that relate to the individuals, and can only be measured when an individual is alive, e.g. white blood cell count, CD4 count

- **external covariates:**
  - variable which changes in a known way, e.g. age, dose of drug
  - variable that exists totally independently of all individuals, e.g. air temperature
Applications and Examples

The extended Cox model is used:

I. When **important covariates change** during a study

- **Framingham Heart study**
  5209 subjects followed since 1948 to examine relationship between risk factors and cardiovascular disease. A particular example:

  **Outcome:** time to congestive heart failure  
  **Predictors:** age, systolic blood pressure, # cigarettes per day

- **Liver Cirrhosis** (Andersen and Gill, p.528)
  Clinical trial comparing treatment to placebo for cirrhosis. The outcome of interest is time to death. Patients were seen at the clinic after 3, 6 and 12 months, then yearly.

  **Fixed covariates:** treatment, gender, age (at diagnosis)  
  **Time-varying covariates:** alcohol consumption, nutritional status, bleeding, albumin, bilirubin, alkaline phosphatase and prothrombin.

- **Recidivism Study** (Allison, p.42)
II. For **cross-over studies**, to indicate change in treatment

- **Stanford heart study** (Cox and Oakes p.129)
  Between 1967 and 1980, 249 patients entered a program at Stanford University where they were registered to receive a heart transplant. Of these, 184 received transplants, 57 died while waiting, and 8 dropped out of the program for other reasons. Does getting a heart transplant improve survival? Here is a sample of the data:

<table>
<thead>
<tr>
<th>Waiting time</th>
<th>transplant?</th>
<th>survival post transplant</th>
<th>total survival</th>
<th>final status</th>
</tr>
</thead>
<tbody>
<tr>
<td>49</td>
<td>2</td>
<td>.</td>
<td>.</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>.</td>
<td>.</td>
<td>1</td>
</tr>
<tr>

<td>15</td>
<td>15</td>
<td>1</td>
</tr>
<tr>
<td>35</td>
<td>1</td>
<td>3</td>
<td>38</td>
<td>1</td>
</tr>
<tr>
<td>17</td>
<td>2</td>
<td>.</td>
<td>.</td>
<td>1</td>
</tr>
<tr>
<td>11</td>
<td>1</td>
<td>46</td>
<td>57</td>
<td>1</td>
</tr>
</tbody>
</table>

(etc)

(survival is not indicated above for those without transplants, but was available in the dataset)

**Naive approach:** Compare the total survival of transplanted and non-transplanted.

**Problem:** Length Bias!
III. For **Competing Risks** Analysis

For example, in cancer clinical trials, “tumor response” (or shrinking of the tumor) is used as an outcome. However, clinicians want to know whether tumor response correlates with survival.

For this purpose, we can fit an extended Cox model for time to death, with tumor response as a time dependent covariate.

IV. For **testing the PH assumption**

For example, we can fit these two models:

(1) **Time independent covariate** $Z_1$

$$\lambda(t, Z) = \lambda_0(t) \exp(\beta_1 * Z_1)$$

The hazard ratio for $Z_1$ is $\exp(\beta_1)$.

(2) **Time dependent covariate** $Z_1$

$$\lambda(t, Z) = \lambda_0(t) \exp(\beta_1 * Z_1 + \beta_2 * Z_1 * t)$$

The hazard ratio for $Z_1$ is $\exp(\beta_1 + \beta_2 t)$.

(note: we may want to replace $t$ by $(t - t_0)$, so that $\exp(\beta_1)$ represents HR at some convenient time, like the median survival time.)

A test of the parameter $\beta_2$ is a test of the PH assumption.

(how do we get the test? ...using the Wald test from the output of second model, or LR test formed by comparing the log-likelihoods of the two models)
Partial likelihood with time-varying covariates

Starting out just as before...
Suppose there are $K$ distinct failure (or death) times, and let $(\tau_1, \ldots, \tau_K)$ represent the $K$ ordered, distinct death times. For now, assume there are no tied death times.

**Risk Set:** Let $\mathcal{R}(t) = \{i : x_i \geq t\}$ denote the set of individuals who are “at risk” for failure at time $t$.

**Failure:** Let $i_j$ denote the label or identity of the individual who fails at time $\tau_j$, including the value of their time-varying covariate during their time in the study

$$\{Z_{i_j}(t), t \in [0, \tau_j]\}$$

**History:** Let $H_j$ denote the “history” of the entire data set, up to the $j$-th death or failure time, including the time of the failure, but not the identity of the one who fails, also including the values of all covariates for everyone up to and including time $\tau_j$.

**Partial Likelihood:** We have seen previously that the partial likelihood can be written as

$$L(\beta) = \prod_{j=1}^{d} P(i_j|H_j)$$

$$= \prod_{j=1}^{d} \frac{\lambda(\tau_j; Z_j(\tau_j))}{\sum_{\ell \in \mathcal{R}(\tau_j)} \lambda(\tau_j; Z_\ell(\tau_j))}$$
Under the PH assumption, this is:

\[ L(\beta) = \prod_{j=1}^{d} \frac{\exp(\beta Z_{jj})}{\sum_{\ell \in R(\tau_j)} \exp(\beta Z_{\ell j})} \]

where \( Z_{\ell j} \) is a short-cut way to denote the value of the covariate vector for the \( \ell \)-th person at the \( j \)-th death time, ie:

\[ Z_{\ell j} = Z_{\ell}(\tau_j) \]

What if \( Z \) is not measured for person \( \ell \) at time \( \tau_j \)?

- use the most recent value (assumes step function)
- interpolate
- impute based on some model

Inference (i.e. estimating the regression coefficients, constructing score tests, etc.) proceeds similarly to standard case. The main difference is that the values of \( Z \) will change at each risk set.

Allison notes that it is very easy to write down a Cox model with time-dependent covariates, but much harder to fit (computationally) and interpret.
Old Example revisited:

Group 0: 4+, 7, 8+, 9, 10+
Group 1: 3, 5, 5+, 6, 8+

Let $Z_1$ be group, and add another fixed covariate $Z_2$

\begin{center}
\begin{tabular}{cccccc}
ID & fail & censor & $Z_1$ & $Z_2$ & $e^{(\beta_1 Z_1 + \beta_2 Z_2)}$\\
1 & 3 & 1 & 1 & 1 & \ $e^{\beta_1+\beta_2}$ \\
2 & 4 & 0 & 0 & 1 & \ $e^{\beta_2}$ \\
3 & 5 & 1 & 1 & 1 & \ $e^{\beta_1+\beta_2}$ \\
4 & 5 & 0 & 1 & 0 & \ $e^{\beta_1}$ \\
5 & 6 & 1 & 1 & 1 & \ $e^{\beta_1+\beta_2}$ \\
6 & 7 & 1 & 0 & 0 & 1 \\
7 & 8 & 0 & 0 & 1 & \ $e^{\beta_2}$ \\
8 & 8 & 0 & 1 & 0 & \ $e^{\beta_1}$ \\
9 & 9 & 1 & 0 & 1 & \ $e^{\beta_2}$ \\
10 & 10 & 0 & 0 & 0 & 1 \\
\end{tabular}

What are the important predictors of recidivism?
Recidivism Example: (cont’d)

Now, we use the indicators of employment status for each of the 52 weeks in the study, recorded as EMP1-EMP52.

We can fit the model in 2 different ways:

```plaintext
proc phreg data=recid;
  model week*arrest(0)=fin age race wexp mar parro prio employed
       / ties=efron;
  array emp(*) emp1-emp52;
  do i=1 to 52;
    if week=i then employed=emp(i);
  end;
run;

*** a shortcut;
proc phreg data=recid;
  model week*arrest(0)=fin age race wexp mar parro prio employed
       / ties=efron;
  array emp(*) emp1-emp52;
  employed=emp(week);
run;

The second way takes 23% less time than the first way, but the results are the same.
```
Recidivism Example: Output

Model WITH employment as time-dependent covariate

<td>0.0001</td>
<td>0.265</td>
</tr>
</tbody>
</table>

Is current employment important?

Do the other covariates change much?

Can you think of any problem with using current employment as a predictor?
Another option for assessing impact of employment

Allison suggests using the employment status of the past week rather than the current week, as follows:

```
proc phreg data=recid;
    where week>1;
    model week*arrest(0)=fin age race wexp mar parro prio employed
         / ties=efron;
    array emp(*) emp1-emp52;
    employed=emp(week-1);
run;
```

The coefficient for \texttt{employed} changes from -1.33 to -0.79, so the risk ratio is about 0.45 instead of 0.27. It is still highly significant with $\chi^2 = 13.1$.

Does this model improve the causal interpretation?

Other options for time-dependent covariates:

- multiple lags of employment status (week-1, week-2, etc.)
- cumulative employment experience (proportion of weeks worked)
Some cautionary notes

- Time-varying covariates must be carefully constructed to ensure interpretability.

- There is no point adding a time-varying covariate whose value changes the same as study time ..... you will get the same answer as using a fixed covariate measured at study entry. For example, suppose we want to study the effect of age on time to death.

We could

1. use age at start of the study as a fixed covariate
2. age as a time varying covariate

However, the results will be the same! Why?
Using time-varying covariates to assess model fit

Suppose we have just fit the following model:

\[
\lambda(t; Z) = \lambda_0(t) \exp(\beta_1 Z_1 + \beta_2 Z_2 + \ldots \beta_p Z_p)
\]

E.g., the nursing home data with gender, marital status and health.

Suppose we want to test the proportionality assumption on health \((Z_p)\)

Create a new variable:

\[
Z_{p+1}(t) = Z_p \gamma(t)
\]

where \(\gamma(t)\) is a known function of time, such as

\[
\gamma(t) = t \\
\text{or } \log(t) \\
\text{or } e^{-pt} \\
\text{or } I_{\{t>t^*\}}
\]

Then testing \(H_0 : \beta_{p+1} = 0\) is a test for non-proportionality
Illustration: Colon Cancer data

Piecewise Cox Model: (Collett, Chapter 10)

A time dependent covariate can be used to create a piecewise PH cox model. Suppose we are interested in comparing two treatments, and:

- $HR=\theta_1$ during the interval $(0, t_1)$
- $HR=\theta_2$ during the interval $(t_1, t_2)$
- $HR=\theta_3$ during the interval $(t_2, \infty)$

Define the following covariates:

- $X$ - treatment indicator
  $(X = 0 \rightarrow \text{standard}, \ X = 1 \rightarrow \text{new treatment})$
- $Z_2$ - indicator of change in HR during 2nd interval
  
  $$Z_2(t) = \begin{cases} 
  1 & \text{if } t \in (t_1, t_2) \text{ and } X = 1 \\
  0 & \text{otherwise}
  \end{cases}$$

- $Z_3$ - indicator of change in HR during 3rd interval
  
  $$Z_3(t) = \begin{cases} 
  1 & \text{if } t \in (t_2, \infty) \text{ and } X = 1 \\
  0 & \text{otherwise}
  \end{cases}$$

The model for the hazard for individual $i$ is:

$$\lambda_i(t) = \lambda_0(t) \exp\{\beta_1 x_i + \beta_2 z_2i(t) + \beta_3 z_3i(t)\}$$

What are the log hazard ratios for an individual on the new treatment relative to one on the standard treatment?
Time varying (or time-dependent) covariates

**Case Study of MAC Disease Trial**

ACTG 196 was a randomized clinical trial to study the effects of combination regimens on prevention of MAC (mycobacterium avium complex) disease, which is one of the most common opportunistic infections in AIDS patients and is associated with high mortality and morbidity.

The **treatment regimens** were:

- clarithromycin (new)
- rifabutin (standard)
- clarithromycin plus rifabutin

This trial enrolled patients between April 1993 and February 1994, and followed patients through August 1995. In February of 1994, the dosage of rifabutin was reduced from 3 capsules per day (450mg) to 2 capsules per day (300mg) due to concern over **uveitis**, an adverse experience resulting in inflammation of the uveal tract in the eyes (about 3-4% of patients reported uveitis). All patients were to reduce their dosage by March 8, 1994. However, some patients had already discontinued the treatment, died, or discontinued the study.

The main intent-to-treat analysis compared the 3 treatment arms without adjusting for this change in dosage.

Other supporting analyses attempted to untangle the effect of this “study wide dose reduction” (SWDR).
Proportion on each treatment arm with SWDR

How well does this model fit?

Let’s take a look at the residual plots...

First, the deviance residuals:

Plotting deviance residuals vs binary covariates is not very useful.
How about the generalized residuals?

(Are they like a sample from a censored unit exponential?)

**Does the Proportional Hazards model fit?**

(i.e., is slope=1, intercept=0)

intercept=0.056

slope=1.028

(based on fitting a regression line to residuals)
We can also look at the log cumulative hazard plots (i.e., \( \log[-\log(S)] \)) versus log time to see whether the lines are parallel for the three treatment groups.

(I have joined the individual points using i=join in the symbol statement, to make them easier to see.)
Shouldn’t we adjust for Baseline CD4 count?

CD4 CD4 Cell Count

Is CD4 count a confounder?

(An analysis stratified by CD4 category gave almost identical results. Other important covariates included CTG (clinical trials group) and Karnofsky status).
What do the deviance residuals look like versus a continuous covariate, like CD4?

We might want to consider some kind of transformation of CD4 count (like log or square root). If we don’t feel comfortable with the linearity of CD4 count, we can also dichotomize it (CD4CAT).
Another way of checking the proportionality assumption is by using the Weighted Schoenfeld residual plots for each covariate.
So far, the graphical techniques have not indicated any major departure from proportional hazards. However, we can test this formally by creating a time dependent covariate for rifabutin and clarithromycin:

\[
\text{riftd}=\text{rif} \times (\text{mactime}-365)/30;
\]

\[
\text{claritd}=\text{clari} \times (\text{mactime}-365)/30;
\]

Even though the dose reduction was only for rifabutin, patients on all 3 arms had to have the dose reduction ... they just took 2 capsules of their placebo, and didn’t know whether it was placebo or active drug.

I have centered the time-dependent covariates at 365 days (one year), so that the HR for rif alone and clari alone will apply at one year. Then I have divided by 30, so that the resulting HR can be interpreted as the change for each month away from 365 days.

**Question:** Can we do this within a data step using the above statements, or do these statements need to be given in the PROC PHREG procedure?

Neither time-dependent covariate was significant.
This analysis also indicated that there are no major departures from proportional hazards for the three treatment arms.

However, it may still be the case that having the study-wide dose reduction had some relationship with MAC disease.

We can assess this by creating a time dependent variable for the SWDR.

**We’ll look at the following models:**

(1) SWDRSTAT as a simple indicator

(2) SWDRSTAT and SWDRTD, with

\[ \text{swdrtd} = \text{swdrstat} \times ((\text{mactime}-365)/30) \]

(3) SWDR as time dependent covariate
Naive model with fixed SWDR indicator (SWDRSTAT):

Dependent Variable: MACTIME  Time to MAC disease (days)
Censoring Variable: MACSTAT  MAC status (1=yes,0=censored)
Censoring Value(s): 0
Ties Handling: BRESLOW

Testing Global Null Hypothesis: BETA=0

Analysis of Maximum Likelihood Estimates

Variable Label

CLARI  1=Clarithromycin arm, 0 otherwise
RIF  1=Rifabutin arm, 0 otherwise
SWDRSTAT  Study Wide Dose Reduction Status

Reduction of dosage from 450mg to 300mg appears to be protective, which seems counter-intuitive
Predicted Baseline Survival Curves:

Another way to see this is through the predicted baseline survival curves. The two lines are for those not on rifabutin, while the x’s and +’s are for those on rifabutin. In each case, the higher line (better prognosis) of the pair is for those who did have the SWDR.

Estimated Survival by SWDR and Rifabutin Status

\]

In the early period after randomization to treatment, reduction of randomized dosage from 450mg to 300mg is associated with a decreased risk of MAC disease. After taking the higher dosage for about 32 months, dropping to the lower dosage has no impact, and as the treatment time increases beyond 32 months, a lower dosage tends to be associated with increased risk of MAC.
3 different ways to code SWDR as time-dependent covariate

proc phreg data=weighted;
  model mactime*macstat(0) = clari rif swdr;

  if (swdrtine>=mactime) then swdr=0;
  else do;
    if swdrstat=1 then swdr=1;
    else swdr=0;
  end;
  test_trt: test clari, rif;
  title2 'I. Time-dependent indicator of dose reduction';

proc phreg data=weighted;
  model mactime*macstat(0) = clari rif swdr;

  if swdrstat=0 or (swdrtine>=mactime) then swdr=0;
  else swdr=1;
  test_trt: test clari, rif;
  title2 'II. Time-dependent indicator of dose reduction';

proc phreg data=weighted;
  model mactime*macstat(0) = clari rif swdr;

  if swdrstat=1 and (swdrtine<mactime) then swdr=1;
  else swdr=0;
  test_trt: test clari, rif;
  title2 'III. Time-dependent indicator of dose reduction';
Output is the same for all 3 cases:

SWDR is still protective? Does this make sense intuitively?

What other methods can we use to account for change in dosage?
Weighted adjusted dose (WAD) analyses

To try to get a better idea of the effect of changing doses of rifabutin on the hazard for MAC disease, I created the following weighted dose of randomized rifabutin:

- Between randomization date and SWDR date
  \[ \Rightarrow \] # Days at 450mg
- Between SWDR date and off-study date
  \[ \Rightarrow \] # Days at 300mg
- Between randomization date and Off-study date
  \[ \Rightarrow \] # Total Days
- Weighted randomized dose

\[
\text{rifwadr} = \frac{\text{days450} + \text{days300}}{\text{totdays}}
\]

- Transformed to number of capsules per day;

\[
\text{rifwadr} = \frac{\text{rifwadr}}{150};
\]

- Also calculated weighted dose *while on treatment* by starting with on treatment date, stopping with off-treatment date, and dividing by the total days on study.

Parametric Survival Analysis

So far, we have focused primarily on nonparametric and semi-parametric approaches to survival analysis, with heavy emphasis on the Cox proportional hazards model:

$$\lambda(t, Z) = \lambda_0(t) \exp(\beta Z)$$

We used the following estimating approach:

- We estimated $\lambda_0(t)$ nonparametrically, using the Kaplan-Meier estimator, or using the Kalbfleisch/Prentice estimator under the PH assumption
- We estimated $\beta$ by assuming a linear model between the log HR and covariates, under the PH model

Both estimates were based on maximum likelihood theory.
There are several reasons why we should consider some alternative approaches based on parametric models:

- The assumption of proportional hazards might not be appropriate (based on major departures)
- If a parametric model actually holds, then we would probably gain efficiency
- We may want to handle non-standard situations like
  - interval censoring
  - incorporating population mortality
- We may want to make some connections with other familiar approaches (e.g. use of the Poisson likelihood)
- We may want to obtain some estimates for use in designing a future survival study.
A simple start: Exponential Regression

- **Observed data:** \((X_i, \delta_i, Z_i)\) for individual \(i\),
  \(Z_i = (Z_{i1}, Z_{i2}, ..., Z_{ip})\) represents a set of \(p\) covariates.

- **Right censoring:** Assume that \(X_i = \min(T_i, U_i)\)

- **Survival distribution:** Assume \(T_i\) follows an exponential distribution with a parameter \(\lambda\) that depends on \(Z_i\), say \(\lambda_i = \Psi(Z_i)\). Then we can write:
  \[ T_i \sim \text{exponential}(\Psi(Z_i)) \]

First, let’s review some facts about the exponential distribution (from our first survival lecture):

\[
f(t) = \lambda e^{-\lambda t} \quad \text{for } t \geq 0
\]

\[
S(t) = P(T \geq t) = \int_t^\infty f(u)du = e^{-\lambda t}
\]

\[
F(t) = P(T < t) = 1 - e^{-\lambda t}
\]

\[
\lambda(t) = \frac{f(t)}{S(t)} = \lambda \quad \text{constant hazard!}
\]

\[
\Lambda(t) = \int_0^t \lambda(u) \, du = \int_0^t \lambda \, du = \lambda t
\]
Now, we say that $\lambda$ is a constant over time $t$, but we want to let it depend on the covariate values, so we are setting

$$\lambda_i = \Psi(Z_i)$$

The hazard rate would therefore be the same for any two individuals with the same covariate values.

Although there are many possible choices for $\Psi$, one simple and natural choice is:

$$\Psi(Z_i) = \exp[\beta_0 + Z_{i1}\beta_1 + Z_{i2}\beta_2 + \ldots + Z_{ip}\beta_p]$$

**WHY?**

- ensures a positive hazard
- for an individual with $Z = 0$, the hazard is $e^{\beta_0}$.

The model is called **exponential regression** because of the natural generalization from regular linear regression
Exponential regression for the 2-sample case:

- Assume we have only a single covariate $Z = Z$, i.e., $p = 1$.

**Hazard Rate:**

$$\Psi(Z_i) = \exp(\beta_0 + Z_i\beta_1)$$

- Define:
  
  $Z_i = 0$ if individual $i$ is in group 0
  
  $Z_i = 1$ if individual $i$ is in group 1

- What is the hazard for group 0?

- What is the hazard for group 1?

- What is the hazard ratio of group 1 to group 0?

- What is the interpretation of $\beta_1$?
Likelihood for Exponential Model

Under the assumption of right censored data, each person has one of two possible contributions to the likelihood:

(a) they have an event at $X_i$ ($\delta_i = 1$) ⇒ contribution is

$$L_i = \frac{S(X_i)}{\lambda(X_i)} = e^{-\lambda X_i} \lambda$$

survive to $X_i$ fail at $X_i$

(b) they are censored at $X_i$ ($\delta_i = 0$) ⇒ contribution is

$$L_i = \frac{S(X_i)}{} = e^{-\lambda X_i}$$

survive to $X_i$

The likelihood is the product over all of the individuals:

$$\mathcal{L} = \prod_i L_i$$

$$= \prod_i \left( \frac{\lambda e^{-\lambda X_i}}{\lambda e^{-\lambda X_i}} \right)^{\delta_i} \left( e^{-\lambda X_i} \right)^{(1-\delta_i)}$$

$$= \prod_i \lambda^{\delta_i} \left( e^{-\lambda X_i} \right)$$
Maximum Likelihood for Exponential

How do we use the likelihood?

• first take the log
• then take the partial derivative with respect to $\beta$
• then set to zero and solve for $\hat{\beta}$
• this gives us the maximum likelihood estimators

The log-likelihood is:

$$\log L = \log \left[ \prod_i \lambda \delta_i \left( e^{-\lambda X_i} \right) \right]$$

$$= \sum_i \left[ \delta_i \log(\lambda) - \lambda X_i \right]$$

$$= \sum_i \left[ \delta_i \log(\lambda) \right] - \sum_i \lambda X_i$$

For the case of exponential regression, we now substitute the hazard $\lambda = \Psi(Z_i)$ in the above log-likelihood:

$$\log L = \sum_i \left[ \delta_i \log(\Psi(Z_i)) \right] - \sum_i \Psi(Z_i) X_i \quad (1)$$
General Form of Log-likelihood for Right Censored Data

In general, whenever we have right censored data, the likelihood and corresponding log likelihood will have the following forms:

\[
\mathcal{L} = \prod_i [\lambda_i(X_i)]^{\delta_i} S_i(X_i)
\]

\[
\log \mathcal{L} = \sum_i [\delta_i \log (\lambda_i(X_i))] - \sum_i \Lambda_i(X_i)
\]

where

- \(\lambda_i(X_i)\) is the hazard for the individual \(i\) who fails at \(X_i\)
- \(\Lambda_i(X_i)\) is the cumulative hazard for an individual at their failure or censoring time

For example, see the derivation of the likelihood for a Cox model on p.11-13 of Lecture 4 notes. We started with the likelihood above, then substituted the specific forms for \(\lambda(X_i)\) under the PH assumption.
Consider our model for the hazard rate:

\[ \lambda = \Psi(Z_i) = \exp[\beta_0 + Z_{i1}\beta_1 + Z_{i2}\beta_2 + \ldots + Z_{ip}\beta_p] \]

We can write this using vector notation, as follows:

Let \[ Z_i = (1, Z_{i1}, \ldots Z_{ip})^T \]

and \[ \beta = (\beta_0, \beta_1, \ldots \beta_p) \]

(Since \( \beta_0 \) is the intercept (i.e., the log hazard rate for the baseline group), we put a “1” as the first term in the vector \( Z_i \).)

Then, we can write the hazard as:

\[ \Psi(Z_i) = \exp[\beta Z_i] \]

Now we can substitute \( \Psi(Z_i) = \exp[\beta Z_i] \) in the log-likelihood shown in (1):

\[ \log L = \sum_{i=1}^{n} \delta_i (\beta Z_i) - \sum_{i=1}^{n} X_i \exp(\beta Z_i) \]
Score Equations

Taking the derivative with respect to $\beta_0$, the score equation is:

$$\frac{\partial \log L}{\partial \beta_0} = \sum_{i=1}^{n} [\delta_i - X_i \exp(\beta Z_i)]$$

For $\beta_k$, $k = 1, \ldots, p$, the equations are:

$$\frac{\partial \log L}{\partial \beta_k} = \sum_{i=1}^{n} \left[ \delta_i Z_{ik} - X_i Z_{ik} \exp(\beta Z_i) \right]$$

$$= \sum_{i=1}^{n} Z_{ik} [\delta_i - X_i \exp(\beta Z_i)]$$

To find the MLE’s, we set the above equations to 0 and solve (simultaneously). The equations above imply that the MLE’s are obtained by setting the weighted number of failures ($\sum_i Z_{ik} \delta_i$) equal to the weighted cumulative hazard ($\sum_i Z_{ik} \Lambda(X_i)$).
To find the variance of the MLE’s, we need to take the second derivatives:

\[
- \frac{\partial^2 \log L}{\partial \beta_k \partial \beta_j} = \sum_{i=1}^{n} Z_{ik} Z_{ij} X_i \exp(\beta Z_i)
\]

Some algebra (see Cox and Oakes section 6.2) reveals that

\[
\text{Var}(\hat{\beta}) = I(\beta)^{-1} = \left[ Z(I - \Pi)Z^T \right]^{-1}
\]

where

- \( Z = (Z_1, \ldots, Z_n) \) is a \((p + 1) \times n\) matrix
  \((p\) covariates plus the “1” for the intercept \(\beta_0\))

- \( \Pi = \text{diag}(\pi_1, \ldots, \pi_n) \) (this means that \(\Pi\) is a diagonal matrix, with the terms \(\pi_1, \ldots, \pi_n\) on the diagonal)

- \(\pi_i\) is the probability that the \(i\)-th person is censored, so \((1 - \pi_i)\) is the probability that they failed.

- **Note:** The information \(I(\beta)\) (inverse of the variance) is proportional to the number of failures, not the sample size. This will be important when we talk about study design.
The Single Sample Problem \((Z_i = 1 \text{ for everyone})\):

First, what is the MLE of \(\bar{\beta}_0\)?

We set \(\frac{1}{\bar{\beta}_0} \frac{\partial \log L}{\partial \beta_0} = \sum_{i=1}^{n} [\delta_i - X_i \exp(\beta_0 Z_i)]\) equal to 0 and solve:

\[
\sum_{i=1}^{n} \delta_i = \sum_{i=1}^{n} [X_i \exp(\beta_0)]
\]

\[
d = \exp(\beta_0) \sum_{i=1}^{n} X_i
\]

\[
\exp(\beta_0) = \frac{d}{\sum_{i=1}^{n} X_i}
\]

\[
\hat{\lambda} = \frac{d}{t}
\]

where \(d\) is the total number of deaths (or events), and \(t = \sum X_i\) is the total person-time contributed by all individuals.

If \(d/t\) is the MLE for \(\lambda\), what does this imply about the MLE of \(\beta_0\)?
Using the previous formula $\text{Var}(\hat{\beta}) = [Z(I - \Pi)Z^T]^{-1}$, what is the variance of $\hat{\beta}_0$?

With some matrix algebra, you can show that it is:

$$\text{Var}(\hat{\beta}_0) = \frac{1}{\Sigma_{i=1}^{n}(1 - \pi_i)} = \frac{1}{d}$$

What about $\hat{\lambda} = e^{\hat{\beta}_0}$?

By the delta method,

$$\text{Var}(\hat{\lambda}) = \hat{\lambda}^2 \text{Var}(\hat{\beta}_0)$$

$$= ?$$
The Two-Sample Problem:

<table>
<thead>
<tr>
<th></th>
<th>Z_i</th>
<th>Subjects</th>
<th>Events</th>
<th>Follow-up</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group 0:</td>
<td>Z_i = 0</td>
<td>n_0</td>
<td>d_0</td>
<td>t_0 = \sum_{i=1}^{n_0} X_i</td>
</tr>
<tr>
<td>Group 1:</td>
<td>Z_i = 1</td>
<td>n_1</td>
<td>d_1</td>
<td>t_1 = \sum_{i=1}^{n_1} X_i</td>
</tr>
</tbody>
</table>

The log-likelihood:

\[
\log \mathcal{L} = \sum_{i=1}^{n} \delta_i (\beta_0 + \beta_1 Z_i) - \sum_{i=1}^{n} X_i \exp(\beta_0 + \beta_1 Z_i)
\]

so

\[
\frac{\partial \log \mathcal{L}}{\partial \beta_0} = \sum_{i=1}^{n} [\delta_i - X_i \exp(\beta_0 + \beta_1 Z_i)]
= (d_0 + d_1) - (t_0 e^{\beta_0} + t_1 e^{\beta_0 + \beta_1})
\]

\[
\frac{\partial \log \mathcal{L}}{\partial \beta_1} = \sum_{i=1}^{n} Z_i [\delta_i - X_i \exp(\beta_0 + \beta_1 Z_i)]
= d_1 - t_1 e^{\beta_0 + \beta_1}
\]

This implies:

\[\hat{\lambda}_1 = e^{\hat{\beta}_0 + \hat{\beta}_1} = ?\]
\[\hat{\lambda}_0 = e^{\hat{\beta}_0} = ?\]
\[\hat{\beta}_0 = ?\]
\[\hat{\beta}_1 = ?\]
**Important Result:**

The maximum likelihood estimates (MLE’s) of the hazard rates under the exponential model are the number of events divided by the person-years of follow-up!

(this result will be relied on heavily when we discuss study design)
Exponential Regression:
Means and Medians

Mean Survival Time
For the exponential distribution, $E(T) = 1/\lambda$.

- **Control Group:**
  $$T_0 = 1/\hat{\lambda}_0 = 1/\exp(\hat{\beta}_0)$$

- **Treatment Group:**
  $$T_1 = 1/\hat{\lambda}_1 = 1/\exp(\hat{\beta}_0 + \hat{\beta}_1)$$

Median Survival Time
This is the value $M$ at which $S(t) = e^{-\lambda t} = 0.5$, so $M = \text{median} = \frac{-\log(0.5)}{\lambda}$

- **Control Group:**
  $$\hat{M}_0 = \frac{-\log(0.5)}{\hat{\lambda}_0} = \frac{-\log(0.5)}{\exp(\hat{\beta}_0)}$$

- **Treatment Group:**
  $$\hat{M}_1 = \frac{-\log(0.5)}{\hat{\lambda}_1} = \frac{-\log(0.5)}{\exp(\hat{\beta}_0 + \hat{\beta}_1)}$$
Exponential Regression:
Variance Estimates and Test Statistics

We can also calculate the variances of the MLE’s as simple functions of the number of failures:

\[
\text{var}(\hat{\beta}_0) = \frac{1}{d_0}
\]

\[
\text{var}(\hat{\beta}_1) = \frac{1}{d_0} + \frac{1}{d_1}
\]

So our test statistics are formed as:

For testing \( H_o : \beta_0 = 0 \):

\[
\chi^2_w = \frac{\left(\hat{\beta}_0\right)^2}{\text{var}(\hat{\beta}_0)}
\]

\[
= \frac{\left[\log(d_0/t_0)\right]^2}{1/d_0}
\]

For testing \( H_o : \beta_1 = 0 \):

\[
\chi^2_w = \frac{\left(\hat{\beta}_1\right)^2}{\text{var}(\hat{\beta}_1)}
\]

\[
= \frac{\left[\log\left(d_1/t_1, t_0 \right)\right]^2}{1/d_0 + 1/d_1}
\]

How would we form confidence intervals for the hazard ratio?
The Likelihood Ratio Test Statistic:
(An alternative to the Wald test)

A likelihood ratio test is based on 2 times the log of the ratio of the likelihoods under the null and alternative. We reject $H_0$ if $2 \log(LR) > \chi^2_{1,0.05}$, where

$$LR = \frac{\mathcal{L}(H_1)}{\mathcal{L}(H_0)} = \frac{\mathcal{L}(\hat{\lambda}_0, \hat{\lambda}_1)}{\mathcal{L}(\lambda)}$$

For a sample of $n$ independent exponential random variables with parameter $\lambda$, the Likelihood is:

$$L = \prod_{i=1}^{n} [\lambda^{\delta_i} \exp(-\lambda x_i)]$$

$$= \lambda^d \exp(-\lambda \sum x_i)$$

$$= \lambda^d \exp(-\lambda n \bar{x})$$

where $d$ is the number of deaths or failures.

The log-likelihood is

$$\ell = d \log(\lambda) - \lambda n \bar{x}$$

and the MLE is

$$\hat{\lambda} = d/(n \bar{x})$$
2-Sample Case: LR test calculations

Data:

Group 0: \( d_0 \) failures among the \( n_0 \) females
mean failure time is \( \bar{x}_0 = \frac{\sum_{i}^{n_0} X_i}{n_0} \)

Group 1: \( d_1 \) failures among the \( n_1 \) males
mean failure time is \( \bar{x}_1 = \frac{\sum_{i}^{n_1} X_i}{n_1} \)

Under the alternative hypothesis:

\[
\mathcal{L} = \lambda_1^{d_1} \exp(-\lambda_1 n_1 \bar{x}_1) \times \lambda_0^{d_0} \exp(-\lambda_0 n_0 \bar{x}_0)
\]

\[
\log(\mathcal{L}) = d_1 \log(\lambda_1) - \lambda_1 n_1 \bar{x}_1 + d_0 \log(\lambda_0) - \lambda_0 n_0 \bar{x}_0
\]

The MLE’s are:

\[
\hat{\lambda}_1 = \frac{d_1}{n_1 \bar{x}_1} \quad \text{for males}
\]

\[
\hat{\lambda}_0 = \frac{d_0}{n_0 \bar{x}_0} \quad \text{for females}
\]

Under the null hypothesis:

\[
\mathcal{L} = \lambda^{d_1+d_0} \exp[-\lambda(n_1 \bar{x}_1 + n_0 \bar{x}_0)]
\]

\[
\log(\mathcal{L}) = (d_1 + d_0) \log(\lambda) - \lambda[n_1 \bar{x}_1 + n_0 \bar{x}_0]
\]

The corresponding MLE is

\[
\hat{\lambda} = \frac{(d_1 + d_0)}{[n_1 \bar{x}_1 + n_0 \bar{x}_0]}
\]
A likelihood ratio test can be constructed by taking twice the difference of the log-likelihoods under the alternative and the null hypotheses:

\[-2 \left[ (d_0 + d_1) \log \left( \frac{d_0 + d_1}{t_0 + t_1} \right) - d_1 \log \left( \frac{d_1}{t_1} \right) - d_0 \log \left( \frac{d_0}{t_0} \right) \right]\]

**Nursing home example:**

**For the females:**
- \(n_0 = 1173\)
- \(d_0 = 902\)
- \(t_0 = 310754\)
- \(\bar{x}_0 = 265\)

**For the males:**
- \(n_1 = 418\)
- \(d_1 = 367\)
- \(t_1 = 75457\)
- \(\bar{x}_1 = 181\)

Plugging these values in, we get a LR test statistic of 64.20.
Hand Calculations using events and follow-up:

By adding up “LOS” for males to get $t_1$ and for females to get $t_0$, I obtained:

- $d_0 = 902$ (females)
  $d_1 = 367$ (males)

- $t_0 = 310754$ (female follow-up)
  $t_1 = 75457$ (male follow-up)

- This yields an estimated log HR:
  $$\hat{\beta}_1 = \log \left[ \frac{d_1/t_1}{d_0/t_0} \right] = \log \left[ \frac{367/75457}{902/310754} \right] = \log(1.6756) = 0.5162$$

- The estimated standard error is:
  $$\sqrt{\text{var}(\hat{\beta}_1)} = \sqrt{\frac{1}{d_1} + \frac{1}{d_0}} = \sqrt{\frac{1}{902} + \frac{1}{367}} = 0.06192$$

- So the Wald test becomes:
  $$\chi^2_w = \frac{\hat{\beta}_1^2}{\text{var}(\hat{\beta}_1)} = \frac{(0.51619)^2}{0.061915} = 69.51$$

- We can also calculate $\hat{\beta}_0 = \log(d_0/t_0) = -5.842$, along with its standard error $se(\hat{\beta}_0) = \sqrt{1/d_0} = 0.0333$

Note that the estimates for $\beta_0$ and $\beta_1$ above are the opposites of what we calculated. I’ll explain why the output has this form when we get to AFT models.
The Weibull Regression Model

At the beginning of the course, we saw that the survivorship function for a Weibull random variable is:

\[ S(t) = \exp\left[-\lambda(t^\kappa)\right] \]

and the hazard function is:

\[ \lambda(t) = \kappa \lambda t^{(\kappa-1)} \]

The Weibull regression model assumes that for someone with covariates \( Z_i \), the survivorship function is

\[ S(t; Z_i) = \exp\left[-\Psi(Z_i)(t^\kappa)\right] \]

where \( \Psi(Z_i) \) is defined as in exponential regression to be:

\[ \Psi(Z_i) = \exp[\beta_0 + Z_{i1}\beta_1 + Z_{i2}\beta_2 + \ldots Z_{ip}\beta_p] \]

For the 2-sample problem, we have:

\[ \Psi(Z_i) = \exp[\beta_0 + Z_{i1}\beta_1] \]
Weibull MLEs for the 2-sample problem:

Log-likelihood:

$$\log \mathcal{L} = \sum_{i=1}^{n} \delta_i \log \left[ \kappa \exp(\beta_0 + \beta_1 Z_i) X_i^{\kappa-1} \right] - \sum_{i=1}^{n} X_i^{\kappa} \exp(\beta_0 + \beta_1 Z_i)$$

$$\Rightarrow \exp(\hat{\beta}_0) = \frac{d_0}{t_{0\kappa}}$$

$$\exp(\hat{\beta}_0 + \hat{\beta}_1) = \frac{d_1}{t_{1\kappa}}$$

where $$t_{j\kappa} = \sum_{i=1}^{n_j} X_i^{\hat{\kappa}}$$ among $$n_j$$ subjects

$$\hat{\lambda}_0(t) = \hat{\kappa} \exp(\hat{\beta}_0) t^{\hat{\kappa}-1}$$

$$\hat{\lambda}_1(t) = \hat{\kappa} \exp(\hat{\beta}_0 + \hat{\beta}_1) t^{\hat{\kappa}-1}$$

$$HR = \frac{\hat{\lambda}_1(t)}{\hat{\lambda}_0(t)} = \exp(\hat{\beta}_1)$$

$$= \exp \left( \frac{d_1/t_{1\kappa}}{d_0/t_{0\kappa}} \right)$$
Weibull Regression:  
Means and Medians

Mean Survival Time
For the Weibull distribution, $E(T) = \lambda^{(-1/\kappa)}\Gamma[(1/\kappa) + 1]$.

- Control Group:
  $T_0 = \hat{\lambda}_0^{(-1/\hat{\kappa})} \Gamma[(1/\hat{\kappa}) + 1]$

- Treatment Group:
  $T_1 = \hat{\lambda}_1^{(-1/\hat{\kappa})} \Gamma[(1/\hat{\kappa}) + 1]$

Median Survival Time
For the Weibull distribution, $M = \text{median} = \left[\frac{-\log(0.5)}{\lambda}\right]^{1/\kappa}$

- Control Group:
  $\hat{M}_0 = \left[\frac{-\log(0.5)}{\hat{\lambda}_0}\right]^{1/\hat{\kappa}}$

- Treatment Group:
  $\hat{M}_1 = \left[\frac{-\log(0.5)}{\hat{\lambda}_1}\right]^{1/\hat{\kappa}}$

where $\hat{\lambda}_0 = \exp(\hat{\beta}_0)$ and $\hat{\lambda}_1 = \exp(\hat{\beta}_0 + \hat{\beta}_1)$. 

Note: the symbol $\Gamma$ is the “gamma” function. If $x$ is an integer, then

$$\Gamma(x) = (x - 1)!$$

In cases where $x$ is not an integer, this function has to be evaluated numerically.

The Weibull regression model is very easy to fit:

- In SAS: use model option `dist=weibull` within the `proc lifereg` procedure
- In STATA: Just specify `dist(weibull)` instead of `dist(exp)` within the `streg` command

Note: to get more information on these modeling procedures, use the online help facilities. For example, in STATA, you can type:

`.help streg`
Weibull in Stata:

```
.streg gender, dist(weibull) nohr

    failure _d: fail
analysis time _t: los
```

In SAS, both the exponential and Weibull are special cases of the general class of *accelerated life models* and the parameter interpretations follow from this approach.

To translate the output of SAS (or Stata using the `ereg` command) for Weibull regression, we have to take the negative of the numbers in the output, divided by the “*_SCALE_*” parameter (σ, or 1/κ).

- \( \hat{\beta}_0 = -\text{INTERCPT}/\_scale\_ \)
- \( \hat{\beta}_1 = -\text{COVARIATE}/\_scale\_ \)

Then we calculate the estimated HR as \( \exp(\hat{\beta}_1) \).

**The MLE’s are:**

- \( \hat{\beta}_0 = -\text{INTERCPT}/\_scale\_ = -5.756/1.627 = -3.537 \)
- \( \hat{\beta}_1 = -\text{COVARIATE}/\_scale\_ = 0.6735/1.625 = 0.414 \)

and the estimated HR is \( \overline{HR} = \exp(\hat{\beta}_1) = \exp(0.414) = 1.513 \).
Weibull Regression: 
Variance Estimates and Test Statistics

It is not so easy to get variance estimates from the output of PROC LIFEREG in SAS or *weibull* in STATA, at least for the parameters we’re interested in.

The variances depend on inverting a $(3 \times 3)$ matrix corresponding to the parameters $\beta_0$, $\beta_1$, and $\kappa$. The MLE for $\kappa$ has to be obtained numerically (i.e., no closed form), so the standard errors also have to be obtained by computer.

**Main objective:** to obtain $s.e.(\hat{\beta}_1)$, so that we can form tests and confidence intervals for the hazard ratio.

The output gives us $\hat{\beta}_1^*$ and $s.e.(\hat{\beta}_1^*)$, where $\hat{\beta}_1 = -\hat{\beta}_1^*/\hat{\sigma}$. If $\sigma$ was a constant, then we could just compute

$$\text{var}(\hat{\beta}_1) = \frac{1}{\hat{\sigma}^4} \text{var}(\hat{\beta}_1^*)$$

but $\sigma$ is also a random variable! Instead, you need to use an approximation for the variance of a ratio of two random variables:

$$\text{var}(\hat{\beta}_1) = \frac{1}{\hat{\sigma}^4} \left[ \hat{\sigma}^2 \text{var}(\hat{\beta}_1^*) + (\hat{\beta}_1^*)^2 \text{var}(\hat{\sigma}) - 2\hat{\beta}_1^* \hat{\sigma} \text{cov}(\hat{\beta}_1^*, \hat{\sigma}) \right]$$

where you get $\text{var}(\hat{\beta}_1^*)$ and $\text{var}(\hat{\sigma})$ by squaring the standard errors of the COVARIATE term and SCALE term, respectively, from the PROC LIFEREG or *weibull* output.
Comparison of Exponential with Kaplan-Meier

We can see how well the Exponential model fits by comparing the survival estimates for males and females under the exponential model, i.e., $P(T \geq t) = e^{(-\lambda z t)}$, to the Kaplan-Meier survival estimates:

![Predicted Survival for Exponential model vs Kaplan–Meier](image-url)
Comparison of Weibull with Kaplan-Meier

We can see how well the Weibull model fits by comparing the survival estimates, \( P(T \geq t) = e^{(-\lambda t^\kappa)} \), to the Kaplan-Meier survival estimates.

![Predicted Survival for Weibull model vs Kaplan–Meier](image)

Which do you think fits best?
Other useful plots for evaluating fit to exponential and Weibull models

• $-\log(\hat{S}(t))$ vs $t$

• $\log[\log(\hat{S}(t))]$ vs $\log(t)$

Why are these useful?

If $T$ is exponential, then $S(t) = \exp(-\lambda t)$

so $\log(S(t)) = -\lambda t$

and $\Lambda(t) = \lambda t$

a straight line in $t$ with slope $\lambda$ and intercept=0

If $T$ is Weibull, then $S(t) = \exp(-(\lambda t)^\kappa)$

so $\log(S(t)) = -\lambda t^\kappa$

then $\Lambda(t) = \lambda t^\kappa$

and $\log(-\log(S(t))) = \log(\lambda) + \kappa \log(t)$

a straight line in $\log(t)$ with slope $\kappa$ and intercept $\log(\lambda)$. 
So we can calculate our estimated $\Lambda(t)$ and plot it versus $t$, and if it seems to form a straight line, then the exponential distribution is probably appropriate for our dataset.

**Plots for nursing home data: $\hat{\Lambda}(t)$ vs $t$**

![Estimated cumulative hazard vs time](image-url)
Or we can plot $\log \hat{A}(t)$ versus $\log(t)$, and if it seems to form a straight line, then the Weibull distribution is probably appropriate for our dataset.

**Plots for nursing home data:** $\log[-\log(\hat{S}(t))]$ vs $\log(t)$
Comparison of Methods

</tbody>
</table>

In General:

\[ \lambda_z(t) = \lambda(t, Z = z) \quad \text{for } z = 0 \text{ or } 1. \]

The hazard rate depends on the value of the covariate \( Z \).

In this case, we are assuming that we only have a single covariate, and it is binary (\( Z = 1 \) or \( Z = 0 \)).
MODELS

Exponential Regression:

\[
\lambda_z(t) = \exp(\beta_0 + \beta_1 Z)
\]

\[\Rightarrow \lambda_0 = \exp(\beta_0)\]

\[\lambda_1 = \exp(\beta_0 + \beta_1)\]

\[HR = \exp(\beta_1)\]

Weibull Regression:

\[
\lambda_z(t) = \kappa \exp(\beta_0 + \beta_1 Z) \ t^{\kappa-1}
\]

\[\Rightarrow \lambda_0 = \kappa \exp(\beta_0) \ t^{\kappa-1}\]

\[\lambda_1 = \kappa \exp(\beta_0 + \beta_1) \ t^{\kappa-1}\]

\[HR = \exp(\beta_1)\]

Proportional Hazards Model:

\[
\lambda_z(t) = \lambda_0(t) \exp(\beta_1)
\]

\[\Rightarrow \lambda_0 = \lambda_0(t)\]

\[\lambda_1 = \lambda_0(t) \exp(\beta_1)\]

\[HR = \exp(\beta_1)\]

396
Remarks

- Exponential model is a special case of the Weibull model with $\kappa = 1$ (note: Collett uses $\gamma$ instead of $\kappa$)

- Exponential and Weibull models are both special cases of the Cox PH model.

**How can you show this?**

- If either the exponential model or the Weibull model is valid, then these models will tend to be more efficient than PH (smaller s.e.’s of estimates). This is because they assume a particular form for $\lambda_0(t)$, rather than estimating it at every death time.
For the Exponential model, the hazards are constant over time, given the value of the covariate $Z_i$:

$$Z_i = 0 \Rightarrow \hat{\lambda}_0 = \exp(\hat{\beta}_0)$$
$$Z_i = 1 \Rightarrow \hat{\lambda}_0 = \exp(\hat{\beta}_0 + \hat{\beta}_1)$$

For the Weibull model, we have to estimate the hazard as a function of time, given the estimates of $\beta_0, \beta_1$ and $\kappa$:

$$Z_i = 0 \Rightarrow \hat{\lambda}_0(t) = \hat{\kappa} \exp(\hat{\beta}_0) t^{\hat{\kappa}-1}$$
$$Z_i = 1 \Rightarrow \hat{\lambda}_1(t) = \hat{\kappa} \exp(\hat{\beta}_0 + \hat{\beta}_1) t^{\hat{\kappa}-1}$$

However, the ratio of the hazards is still just $\exp(\hat{\beta}_1)$, since the other terms cancel out.
Here’s what the estimated hazards look like for the nursing home data:

Estimated Hazards for Weibull & Exponential by Gender

- Exponential Hazard: Female

The Accelerated Failure Time Model

The general form of an accelerated failure time (AFT) model is:

\[
\log(T_i) = \beta_{AFT}Z_i + \sigma \epsilon
\]

where

- \(\log(T_i)\) is the log of a survival time
- \(\beta_{AFT}\) is the vector of AFT model parameters corresponding to the covariate vector \(Z_i\)
- \(\epsilon\) is a random “error” term
- \(\sigma\) is a scale factor

In other words, we can model the log-survival times as a linear function of the covariates.

PROC LIFEREG in SAS and the \texttt{streg} command in STATA (without the exponential or weibull option) all use this “log-linear” model formulation for fitting parametric models.
By choosing different distributions for $\epsilon$, we can obtain different parametric distributions:

- Exponential
- Weibull
- Gamma
- Log-logistic
- Normal
- Lognormal

We can compare the predicted survival under any of these parametric distributions to the KM estimated survival to see which one seems to fit best.

Once we decide on a certain class of model (say, Gamma), we can evaluate the contributions of covariates by finding the MLE’s, and constructing Wald, Score, or LR tests of the covariate effects.
We can motivate the AFT model by first demonstrating the following two relationships:

- **1. For the Exponential Model:**
  If the failure times $T_i = T(Z_i)$ follow an exponential distribution, i.e., $S_i(t) = e^{-\lambda_i t}$ with $\lambda_i = \exp(\beta Z_i)$, then
  \[
  \log(T_i) = -\beta Z_i + \epsilon
  \]
  where $\epsilon$ follows an extreme value distribution (which just means that $e^\epsilon$ follows a unit exponential distribution).

- **2. For the Weibull Model:**
  If the failure times $T_i = T(Z_i)$ follow a Weibull distribution, i.e., $S_i(t) = e^{\lambda_i t^\kappa}$ with $\lambda_i = \exp(\beta Z_i)$, then
  \[
  \log(T_i) = -\sigma \beta Z_i + \sigma \epsilon
  \]
  where $\epsilon$ again follows an extreme value distribution, and $\sigma = 1/\kappa$.

In other words, both the Exponential and Weibull model can be written in the form of a log-linear model for the survival times, if we choose the right distribution for $\epsilon$.  

406
The log-linear form for the exponential can be derived by:

(1) Creating a new variable $T_0 = T_Z \times \exp(\beta Z_i)$

(2) Taking the log of $T_Z$, yielding $\log(T_Z) = \log \left( \frac{T_0}{\exp(\beta Z_i)} \right)$

**Step (1):** For an exponential model, recall that:

$$S_i(t) = Pr(T_Z \geq t) = e^{-\lambda t}, \quad \text{with } \lambda = \exp(\beta Z_i)$$

It follows that $T_0 \sim \exp(1)$:

$$S_0(t) = Pr(T_0 \geq t) = Pr(T_Z \cdot \exp(\beta Z) \geq t)$$

$$= Pr(T_Z \geq t \exp(-\beta Z))$$

$$= \exp[-\lambda t \exp(-\beta Z)]$$

$$= \exp[-\exp(\beta Z) t \exp(-\beta Z)]$$

$$= \exp(-t)$$

**Step (2):** Now take the log of the survival time:

$$\log(T_Z) = \log \left( \frac{T_0}{\exp(\beta Z_i)} \right)$$

$$= \log(T_0) - \log(\exp(\beta Z_i))$$

$$= -\beta Z_i + \log(T_0)$$

$$= -\beta Z_i + \epsilon$$

where $\epsilon = \log(T_0)$ follows the **extreme value** distribution.
Relationship between Exponential and Weibull

If $T_Z$ has a Weibull distribution, i.e., $S(t) = e^{-\lambda t^\kappa}$ with $\lambda = \exp(\beta Z_i)$, then you can show that the new variable

$$T^*_Z = T^*_Z$$

follows an exponential distribution with parameter $\exp(\beta Z_i)$. Based on the previous page, we can therefore write:

$$\log(T^*) = -\beta Z + \epsilon$$

(where $\epsilon$ has an extreme value distribution.)

But since $\log(T^*) = \log(T^\kappa) = \kappa \times \log(T)$, we can write:

$$\log(T) = \log(T^*)/\kappa$$

$$= (1/\kappa) (-\beta Z_i + \epsilon)$$

$$= -\sigma \beta Z_i + \sigma \epsilon$$

where $\sigma = 1/\kappa$. 
This motivates the following general definition of the Accelerated Failure Time Model by:

\[
\log(T_i) = \beta_{AFT} Z_i + \sigma \epsilon
\]

where \( \epsilon \) is a random “error” term, \( \sigma \) is a scale factor, \( Y \) is the log of a survival random variable, and

\[
\beta_{AFT} = -\sigma \beta_e
\]

where \( \beta_e \) came from the hazard \( \lambda = \exp(\beta Z) \).

The defining feature of an AFT model is:

\[
S(t; Z) = S_i(t) = S_0(\phi t)
\]

That is, the effect of covariates is to accelerate (stretch) or decelerate (shrink) the time-scale.

Effect of AFT on hazard:

\[
\lambda_i(t) = \phi \lambda_0(\phi t)
\]
One way to interpret the AFT model is via its effect on median survival times. If \( S_i(t) = 0.5 \), then \( S_0(\phi t) = 0.5 \). This means:

\[
M_i = \phi M_0
\]

**Interpretation:**

- For \( \phi < 1 \), there is an acceleration of the endpoint
  (if \( M_0 = 2 \)yrs in control and \( \phi = 0.5 \), then \( M_i = 1 \)yr.
- For \( \phi > 1 \), there is a stretching or delay in endpoint
- In general, the lifetime of individual \( i \) is \( \phi \) times what they would have experienced in the reference group

Since \( \phi \) must be positive and a function of the covariates, we model \( \phi = \exp(\beta \mathbf{Z}_i) \).
When does Proportional hazards = AFT?

According to the proportional hazards model:

\[ S(t) = S_0(t)^{\exp(\beta Z_i)} \]

and according to the accelerated failure time model:

\[ S(t) = S_0(t \exp(\beta Z_i)) \]

Say \( T_i \sim \text{Weibull}(\lambda, \kappa) \). Then \( \lambda(t) = \lambda \kappa t^{(\kappa-1)} \)

Under the AFT model:

\[
\lambda_i(t) = \phi \lambda_0(\phi t) \\
= e^{\beta Z_i} \lambda_0(e^{\beta Z_i t}) \\
= e^{\beta Z_i} \lambda_0(\kappa) \left( e^{\beta Z_i t} \right)^{(\kappa-1)} \\
= \left( e^{\beta Z_i} \right)^{\kappa} \lambda_0(\kappa t^{(\kappa-1)}) \\
= \left( e^{\beta Z_i} \right)^{\kappa} \lambda_0(t)
\]

But this looks just like the PH model:

\[
\lambda_i(t) = \exp(\beta^* Z_i) \lambda_0(t)
\]

It turns out that the Weibull distribution (and exponential, since this is just a special case of a Weibull with \( \kappa = 1 \)) is the only one for which the accelerated failure time and proportional hazards models coincide.
Special cases of AFT models

- Exponential regression: $\sigma = 1$, $\epsilon$ following the extreme value distribution.
- Weibull regression: $\sigma$ arbitrary, $\epsilon$ following the extreme value distribution.
- Lognormal regression: $\sigma$ arbitrary, $\epsilon$ following the normal distribution.

Examples in stata: Using the STREG command, one has the following options of distributions for the log-survival times:

```stata
. streg trt, dist(lognormal)
```

- exponential
- weibull
- gompertz
- lognormal
- loglogistic
- gamma
. streg gender, dist(exponential) nohr

| _t | Coef.   | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----|---------|-----------|-----|------|----------------------|
| gender | .516186 | .0619148  | 8.337 | 0.000 | (.3948352, .6375368) |

. streg gender, dist(weibull) nohr

| _t | Coef.   | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----|---------|-----------|-----|------|----------------------|
| gender | .4138082 | .0621021  | 6.663 | 0.000 | (.2920903, .5355261) |
| 1/p | 1.627501 | .0377726  |       |      | (1.555127, 1.703243) |

. streg gender, dist(lognormal)

| _t | Coef.   | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----|---------|-----------|-----|------|----------------------|
| gender | -.6743434 | .1127352 | -5.982 | 0.000 | (-.8953002, -.4533866) |
| _cons | 4.957636 | .0588939 | 84.179 | 0.000 | (4.842206, 5.073066)  |
| sigma | 1.94718 | .040584  |       |      | (1.86924, 2.028371)   |

. streg gender, dist(gamma)

| _t | Coef.   | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|----|---------|-----------|-----|------|----------------------|
| gender | -.6508469 | .1147116 | -5.674 | 0.000 | (-.8756774, -.4260163) |
| _cons | 4.788114 | .1020906 | 46.901 | 0.000 | (4.58802, 4.988208)   |
| sigma | 1.97998 | .0429379 |       |      | (1.897586, 2.065951)  |
This gives a good idea of the sensitivity of the test of gender to the choice of model. It is also easy to get predicted survival curves under any of the parametric models using the following:

```
. streg gender, dist(gamma)
. stcurv, survival
```

The options HAZARD and CUMHAZ can also be substituted for SURVIVAL above to obtain plots.
AFT models in SAS

```sas
proc lifereg data=pop covout outest=survres;

  model los*censor(1)=gender /dist=exponential;
  model los*censor(1)=gender /dist=weibull;
  model los*censor(1)=gender /dist=gamma;
  model los*censor(1)=gender /dist=normal;

```

Other options are lognormal, logistic, and log-logistic. The default is to model log of response. Can specify ”NOLOG” for no log-transformation. In this case, ”normal” is the same as ”lognormal.”

Designing a Survival Study

We will focus on the power of tests based on the exponential distribution and the logrank test.

- As in standard designs, the power depends on
  - The Type I error (significance level)
  - The difference of interest, $\Delta$, under $H_a$.

- A notable difference from the usual scenario is that power depends on the **number of failures**, not the total sample size.

- In practice, designing a survival study involves deciding how many patients or individuals to enter, as well as how long they should be followed.

- Designs may be **fixed sample size** or **sequential**
  (More on this later!)

Review of power calculations for 2-sample normal

Suppose we have the following data:

- Group 1: \((Y_{11}, \ldots Y_{1n_1})\)
- Group 0: \((Y_{01}, \ldots Y_{0n_0})\)

and make the following assumptions:

\[ Y_{1j} \sim \mathcal{N}(\mu_1, \sigma^2) \quad Y_{0j} \sim \mathcal{N}(\mu_0, \sigma^2) \]

Our objective is to test:

\[ H_0 : \mu_1 = \mu_0 \quad \Rightarrow \quad H_0 : \Delta = 0 \quad \text{ where } \Delta = \mu_1 - \mu_0 \]

The standard test is based on the \(Z\) statistic:

\[ Z = \frac{\bar{Y}_1 - \bar{Y}_0}{s \sqrt{\frac{1}{n_1} + \frac{1}{n_0}}} \]

where \(s^2\) is the pooled sample variance (we are assuming equal variances here). This test statistic follows a \(\mathcal{N}(0,1)\) distribution under \(H_0\).

If the sample sizes are equal in the two arms, \(n_0 = n_1 = n/2\), (which will maximize the power), then we have the simpler form:

\[ Z = \frac{\bar{Y}_1 - \bar{Y}_0}{s \sqrt{\frac{1}{n/2} + \frac{1}{n/2}}} = \frac{\bar{Y}_1 - \bar{Y}_0}{2s/\sqrt{n}} \]
The steps to follow in calculating the sample size are:

1. Determine the critical value, \( c \), for rejecting the null when it is true.
2. Calculate the probability of rejecting the null when the alternative is true, substituting \( c \) from above.
3. Rewrite the expression in terms of the sample size for a given power.

**Step (1):**

Set the significance level, \( \alpha \), equal to the probability of rejecting the null hypothesis when it is true:

\[
\alpha = Pr \left( \left| Y_1 - Y_0 \right| > c \mid H_0 \right)
\]

\[
= Pr \left( \frac{\left| Y_1 - Y_0 \right|}{2s/\sqrt{n}} > \frac{c}{2s/\sqrt{n}} \mid H_0 \right)
\]

\[
= Pr \left( \left| Z \right| > \frac{c}{2s/\sqrt{n}} \right) = 2 \cdot \Phi \left( \frac{c}{2s/\sqrt{n}} \right)
\]

So \( z_{1-\alpha/2} = \frac{c}{2s/\sqrt{n}} \)

or \( c = \frac{z_{1-\alpha/2} \cdot 2s}{\sqrt{n}} \)

Note that \( z_\gamma \) is the value such that \( \Phi(z_\gamma) = Pr(Z < z_\gamma) = \gamma \).
Step (2):

Calculate the probability of rejecting the null when $H_a$ is true. Start out by writing down the probability of a Type II error:

$$\beta = Pr\left(\text{accept } H_0 \mid H_a\right)$$

so

$$1 - \beta = Pr\left(\text{reject } H_0 \mid H_a\right)$$

$$= Pr\left(|\overline{Y}_1 - \overline{Y}_0| > c \mid H_a\right)$$

$$= Pr\left(\left|\frac{|\overline{Y}_1 - \overline{Y}_0| - \Delta}{2s/\sqrt{n}}\right| > \frac{c - \Delta}{2s/\sqrt{n}} \mid H_a\right)$$

$$= Pr\left(Z > \frac{c - \Delta}{2s/\sqrt{n}}\right)$$

so we get

$$z_\beta = -z_{1-\beta} = \frac{c - \Delta}{2s/\sqrt{n}}$$

Now we substitute $c$ from Step (1):

$$-z_{1-\beta} = \frac{z_{1-\alpha/2} \frac{2s}{\sqrt{n}} - \Delta}{2s/\sqrt{n}}$$

$$= z_{1-\alpha/2} - \frac{\Delta}{2s \sqrt{n}}$$
Step (3):

Now rewrite the equation in terms of sample size for a given power, $1 - \beta$, and significance level, $\alpha$:

$$
 z_{1-\alpha/2} + z_{1-\beta} = \frac{\Delta}{2s/\sqrt{n}} \\
 = \frac{\Delta \sqrt{n}}{2s} \\
\implies n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2 4s^2}{\Delta^2}
$$

Notes:

The power is an increasing function of the standardized difference:

$$
\mu_T(\Delta) = \frac{\Delta}{2s/\sqrt{n}}
$$

This is just the number of standard errors between the two means, under the assumption of equal variances.

1. As $n$ increases, the power increases.
2. For fixed $n$, the power increases with $\Delta$.
3. For fixed $n$ and $\Delta$, the power decreases with $s$.
4. Assigning equal numbers of patients to the two groups ($n_1 = n_0 = n/2$) is best in terms of maximizing power.
An Example:

\[ n = \frac{\left( z_{1-\frac{\alpha}{2}} + z_{1-\beta} \right)^2 4s^2}{\Delta^2} \]

Say we want to derive the total sample size required to yield 90% power for detecting a difference of 0.5 standard deviations between means, based on a two-sided 0.05 level test.

\[
\alpha = 0.05 \\
z_{1-\frac{\alpha}{2}} = 1.96 \\
\beta = 0.10 \\
z_{1-\beta} = z_{0.90} = 1.28
\]

\[ n = \frac{(1.96 + 1.28)^2 4s^2}{\Delta^2} \approx \frac{42}{\Delta^2} s^2 \]

For a 0.5 standard deviation difference, \( \Delta/s = 0.5 \), so

\[ n \approx \frac{42}{(0.5)^2} = 168 \]

If you end up with \( n < 30 \), then you should be using the t-distribution rather than the normal to calculate critical values, and then the process is iterative.
Survival Studies: Comparing Proportions of Events

In some cases, the sample size for a survival trial is based on a crude comparison of the proportion of events at some fixed point in time.

In this case, we can apply the results just shown to get sample sizes, based on the normal approximation to the binomial:

Define:

- $P_c$ probability of event in control arm by time $t$
- $P_e$ probability of event in “experimental” arm by time $t$

The number of patients required per treatment arm based on a chi-square test comparing binomial proportions is:

$$N = \frac{\{z_{1-\alpha/2}\sqrt{2\overline{P}(1-\overline{P})} + z_{1-\beta}\sqrt{P_c(1-P_c) + P_e(1-P_e)}\}^2}{(P_c - P_e)^2}$$

where $\overline{P} = (P_e + P_c)/2$

(This looks slightly different because the variance is not the same under $H_o$ and $H_a$, as was the case in the normal previous example.)
Notes on comparing proportions of failures:

- Use of chi-square test is best when $0.2 < P_e, P_c < 0.8$

- Should have $\geq 15$ patients in each cell of the (2x2) table

- For smaller sample sizes, use Fisher’s exact test to motivate power calculations

- Efficiency vs logrank test is near 100% for studies with short durations relative to the median event time

**What does this mean in terms of the event rates? High or low?**

- Calculation of sample size for comparing proportions often provides an upper bound to those based on comparison of survival distributions
Sample size based on the logrank test

**Recap:** Consider a two group survival problem, with equal numbers of individuals in the two groups (say \(n_0\) in group 0 and \(n_1\) in group 1). Let \(\tau_1, \ldots, \tau_K\) represent the \(K\) ordered, distinct failure times, and at the \(j\)-th event time:

<table>
<thead>
<tr>
<th>Group</th>
<th>Die/Fail</th>
<th>Yes</th>
<th>No</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td></td>
<td>(d_{0j})</td>
<td>(r_{0j} - d_{0j})</td>
<td>(r_{0j})</td>
</tr>
<tr>
<td>1</td>
<td></td>
<td>(d_{1j})</td>
<td>(r_{1j} - d_{1j})</td>
<td>(r_{1j})</td>
</tr>
<tr>
<td>Total</td>
<td></td>
<td>(d_j)</td>
<td>(r_j - d_j)</td>
<td>(r_j)</td>
</tr>
</tbody>
</table>

where \(d_{0j}\) and \(d_{1j}\) are the number of deaths (events) in group 0 and 1, respectively, at the \(j\)-th event time, and \(r_{0j}\) and \(r_{1j}\) are the corresponding numbers at risk.

**The logrank test is:** (z-statistic version)

\[
Z_{LR} = \frac{\sum_{j=1}^{K} (d_{1j} - e_j)}{\sqrt{\sum_{j=1}^{K} v_j}}
\]

with \(e_j = d_j \frac{r_{1j}}{r_j}\)

\(v_j = r_{1j} r_{0j} d_j (r_j - d_j) / [r_j^2 (r_j - 1)]\)
**Distribution of the logrank statistic**

Suppose that the hazard rates in the two groups are $\lambda_0(t)$ and $\lambda_1(t)$, with hazard ratio

$$\theta = e^\beta = \frac{\lambda_1(t)}{\lambda_0(t)}$$

and suppose we are interested in testing $H_0 : \beta = \ln(\theta) = 0$ (which is equivalent to testing $H_0 : \theta = 1$.)

[Note: we will use $\ln(\theta)$ rather than $\beta$ in the following, so that there is no confusion with the Type II error rate]

It is possible to show that

- if there are no ties, and
- we are “near” $H_0$:

then:

- $E(d_{1j} - e_j | d_{1j}, d_{0j}, r_{1j}, r_{0j}) \approx \ln(\theta)/4$
- $v_j \approx 1/4$

So, at a point $\ln(\theta)$ in the alternative, we get:

$$Z_{LR} \approx \frac{\sum_{j=1}^{K} \ln(\theta)/4}{\sqrt{\sum_{j=1}^{K} 1/4}} = \frac{d \ln(\theta)/4}{\sqrt{d/4}} = \frac{\sqrt{d} \ln(\theta)}{2}$$

and $Z_{LR} \sim N(\ln(\theta)\sqrt{d}/2, 1)$
Heuristic Proof:

\[ E(d_{1j}|d_{1j}, d_{0j}, r_{1j}, r_{0j}) = Pr(d_{1j} = 1|d_j = 1, r_{1j}, r_{0j}) \]

\[ = \frac{r_{1j}\lambda_0\theta}{r_{1j}\lambda_0\theta + r_{0j}\lambda_0} \]

\[ = \frac{r_{1j}\theta}{r_{1j}\theta + r_{0j}} \]

\[ = \frac{r_{1j}}{r_{1j} + r_{0j}} + ln(\theta) \left[ \frac{r_{1j}r_{0j}}{(r_{1j} + r_{0j})^2} \right] \]

But \( e_j = r_{1j}/(r_{1j} + r_{0j}) \), so:

\[ E(d_{1j}|d_{1j}, d_{0j}, r_{1j}, r_{0j}) - e_j = ln(\theta) \left[ \frac{r_{1j}r_{0j}}{(r_{1j} + r_{0j})^2} \right] \]

If \( n_0 = n_1 \), then near \( H_0 \), \( r_{1j} \approx r_{0j} \), hence,

\[ E(d_{1j}|d_{1j}, d_{0j}, r_{1j}, r_{0j}) - e_j = ln(\theta) / 4 \]

Similarly, with no ties, we have

\[ v_j = r_{1j}r_{0j}/r_j^2 \approx 1/4 \]
This can also be derived via the partial likelihood:

We can write the partial likelihood as:

\[
l(\beta) = \log \left[ \prod_{j=1}^{n} \left( \frac{e^{\beta Z_j}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right)^{\delta_j} \right]
\]

\[
= \sum_{j=1}^{n} \delta_j \left[ \beta Z_j - \log \left( \sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}} \right) \right]
\]

and then the “score” (partial derivative of log-likelihood) becomes:

\[
U(\beta) = \frac{\partial}{\partial \beta} l(\beta)
\]

\[
= \sum_{j=1}^{n} \delta_j \left[ Z_j - \frac{\sum_{\ell \in R(\tau_j)} Z_{\ell} e^{\beta Z_{\ell}}}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right]
\]

We can write the “information” (minus second partial derivative of the log-likelihood) as:

\[
-\frac{\partial^2}{\partial \beta^2} l(\beta) = \sum_{j=1}^{n} \delta_j \left[ \frac{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}} \sum_{\ell \in R(\tau_j)} Z_{\ell} e^{\beta Z_{\ell}} - \left( \sum_{\ell \in R(\tau_j)} Z_{\ell} e^{\beta Z_{\ell}} \right)^2}{\sum_{\ell \in R(\tau_j)} e^{\beta Z_{\ell}}} \right]
\]

The logrank statistic (with no ties) is equivalent to the score statistic for testing \( \beta = 0 \):

\[
Z_{LR} \sim U(0) / \sqrt{I(0)}
\]

By a Taylor series expansion:

\[
U(0) \approx U(\beta) - \beta \frac{\partial U}{\partial \beta}(0)
\]

\[
E[U(0)] \approx \beta d / 4 \quad \text{and} \quad I(0) \approx d / 4
\]
**Power of the Logrank Test**

Using a similar argument to before, the power of the logrank test (based on a two-sided $\alpha$ level test) is approximately:

$$\text{Power}(\theta) \approx 1 - \Phi \left[ z_{1-\frac{\alpha}{2}} - \ln(\theta) \sqrt{d/2} \right]$$

**Note:** Power depends only on $d$ and $\theta$!

We can easily solve for the required number of events to achieve a certain power at a specified value of $\theta$:

To yield $\text{power}(\theta) = 1 - \beta$, we want $d$ so that

$$1 - \beta = 1 - \Phi \left( z_{1-\frac{\alpha}{2}} - \ln(\theta) \sqrt{d/2} \right)$$

$$\Rightarrow \quad z_\beta = z_{1-\frac{\alpha}{2}} - \ln(\theta) \sqrt{d/2}$$

$$\Rightarrow \quad d = \frac{4 \left( z_{1-\frac{\alpha}{2}} - z_\beta \right)^2}{[\ln(\theta)]^2}$$

or

$$d = \frac{4 \left( z_{1-\frac{\alpha}{2}} + z_{1-\beta} \right)^2}{[\ln(\theta)]^2}$$
Example:

Say we were planning a 2-arm study, and wanted to be able to detect a hazard ratio of 1.5 with 90% power at a 2-sided significance level of $\alpha = 0.05$.

Required number of events:

\[
\begin{align*}
    d &= \frac{4 \left(z_{1-\frac{\alpha}{2}} + z_{1-\beta}\right)^2}{[ln(\theta)]^2} \\
    &= \frac{4(1.96 + 1.282)^2}{[ln(1.5)]^2} \\
    &\approx \frac{42}{0.1644} = 256
\end{align*}
\]

# Events required for various Hazard Ratios

<table>
<thead>
<tr>
<th>Hazard Ratio</th>

</tbody>
</table>

Most studies are designed to detect a hazard ratio of 1.5-2.0.
Practical Considerations

- How do we decide on $\theta$?
- How do we translate numbers of failures to numbers of patients?

Hazard ratios for the exponential distribution

The hazard ratio from two exponential distributions can be easily translated into more intuitively interpretable quantities:

**Median:**

If $T_i \sim exp(\lambda_i)$, then

$$\text{Median}(T_i) = -\ln(0.5)/\lambda_i$$

It follows that

$$\frac{\text{Median}(T_1)}{\text{Median}(T_0)} = \frac{\lambda_0}{\lambda_1} = e^{-\beta} = \frac{1}{\theta}$$

Hence, doubling the median survival of a treated compared to a control group will correspond to halving the hazard.
R-year survival rates

Suppose the R-year survival rate in group 1 is $S_1(R)$ and in group 0 is $S_0(R)$. Under the exponential model:

$$S_i(R) = exp(-\lambda_i R)$$

Hence,

$$\frac{ln(S_1(R))}{ln(S_0(R))} = \frac{-\lambda_1 R}{-\lambda_0 R} = \frac{\lambda_1}{\lambda_0} = e^\beta = \theta$$

Hence, doubling the hazard rate from group 1 to group 0 will correspond to doubling the log of the R-year survival rate. Note that this result does not depend on R!.

Example: Suppose the 5-year survival rate on treatment A is 20% and we want 90% power to detect an improvement of that rate to 30%. The corresponding hazard ratio of treated to control is:

$$\frac{ln(0.3)}{ln(0.2)} = \frac{-1.204}{-1.609} = 0.748$$

From our previous formula, the number of events (deaths) needed to detect this improvement with 90% power, based on a 2-sided 5% level test is:

$$d = \frac{4(1.96 + 1.282)^2}{[ln(0.748)]^2} = 499$$
Translating to Number of Enrolled Patients

First, suppose that we will enter \( N \) patients into our study at time 0, and will then continue the study for \( F \) units of time.

Under \( H_0 \), the probability that an individual will fail during the study is:

\[
Pr(\text{fail}) = \int_0^F \lambda_0 e^{-\lambda_0 t} dt
\]

\[
= 1 - e^{-\lambda_0 F}
\]

Hence, if our calculations say we need \( d \) failures, then to decide how many patients to enter, we simply solve

\[
d = (N/2)(1 - e^{-\lambda_0 F}) + (N/2)(1 - e^{-\lambda_1 F})
\]

To solve the above equation for \( N \), we need to supply values of \( F \) and \( d \). In other words, here we are already deciding what HR we want to detect (with what power, etc), and for how long we are going to follow patients. What we get is the total number of patients we need to enroll in order to observe the desired number of events in \( F \) units of follow-up time.
Example: Suppose we want to detect a 50% improvement in the median survival from 12 months to 18 months with 80% power at $\alpha = 0.05$, and we plan on following patients for 3 years (36 months).

We can use the two medians to calculate both the parameters $\lambda_0$ and $\lambda_1$ and the hazard ratio, $\theta$:

$$\text{Median}(T_i) = -\ln(0.5)/\lambda_i$$

so

$$\lambda_1 = \frac{-\ln(0.5)}{M1} = \frac{0.6931}{18} = 0.0385$$

$$\lambda_0 = \frac{-\ln(0.5)}{M0} = \frac{0.6931}{12} = 0.0578$$

$$\theta = \frac{\lambda_1}{\lambda_0} = \frac{0.0385}{0.0578} = \frac{12}{18} = 0.667$$

and from our previous table, # events required is $d = 191$ (same for $\theta = 1.5$ as it is for $1/1.5=0.667$).

So we need to solve:

$$191 = \frac{N}{2}(1 - e^{-0.0578 \times 36}) + \frac{N}{2}(1 - e^{-0.0385 \times 36})$$

$$= \frac{N}{2}(0.875) + \frac{N}{2}(0.7500) = \frac{N}{2}(1.625)$$

$$\Rightarrow N = 235$$

(for practical reasons, we would probably round up to 236 and randomize 118 patients to each treatment arm)
A more realistic accrual pattern

In reality, not everyone will enter the study on the same day. Instead, the accrual will occur in a “staggered” manner over a period of time.

The standard assumption:
Suppose individuals enter the study uniformly over an accrual period lasting $A$ units of time, and that after the accrual period, follow-up will continue for another $F$ units of time.

To translate $d$ to $N$, we need to calculate the probability that a patient fails under this accrual and follow-up scenario.

\[
Pr(\text{fail}) = \int_0^A Pr(\text{fail}|\text{enter at } a) f(a) \, da
\]
\[
= 1 - \frac{\int_0^A S(a + F) \, da}{A}
\]

(2)

Then solve:
\[
d = (N/2)Pr(\text{fail}; \lambda_0) + (N/2)Pr(\text{fail}; \lambda_1)
\]
\[
= (N/2)P_c + (N/2)P_e
\]
\[
= (N/2)(P_c + P_e)
\]

If we now solve for $N$ (substituting in formula for $d$), we get:
\[
N = \frac{2 \, d}{(P_c + P_e)}
\]
\[
N = \frac{8 \left( z_{1-\frac{\alpha}{2}} + z_{1-\beta} \right)^2}{\left[ \ln(\theta) \right]^2} \frac{1}{(P_c + P_e)}
\]
How can we get $P_c$ and $P_e$ from (2)?

If we assume that the exponential distribution holds, then we can solve (2) to obtain:

$$
P_i = 1 - \frac{\exp(-\lambda_i F)(1 - \exp(-\lambda_i A))}{\lambda_i A} \tag{3}
$$

(for $i = c, e$)

Freedman suggested an approximation for $P_c$ and $P_e$, by computing the probability of an event at the median duration of follow-up, $(A/2 + F)$:

$$
P_i = Pr(\text{fail}; \lambda_i) = 1 - \exp[-\lambda_i(A/2 + F)] \tag{4}
$$

He showed that this approximation works pretty well for the exponential distribution (i.e., it gives values close to (3)).
An alternative formulation

Rubenstein, Gail, and Santner (1981) suggest the following approach for calculating the total sample size that must be enrolled:

\[ N = \frac{2 \left( z_{1-\frac{\alpha}{2}} + z_{1-\beta} \right)^2}{[\ln(\theta)]^2} \left[ \frac{1}{P_c} + \frac{1}{P_e} \right] \]

where \( P_c \) and \( P_e \) are the expected proportion of patients or individuals who will fail (have an event) on the control and treatment arms.

How do we calculate (estimate) \( P_c \) and \( P_e \)?

- using the general formula for a distribution \( S \) given in (2)
- using the exact formula for an exponential distribution given in (3)
- using the approximation given by (4)

**Note:** all of these formulas can be modified for **unequal** assignment to treatment (or exposure) groups by changing \( N/2 \) in the formulas on p.17-19 to \( (qc \times N) \) and \( (qe \times N) \), where \( qc \) and \( qe \) are the proportions assigned to the control and exposed groups, respectively.
Freedman’s Approach (1982)

Freedman’s approach is based on the logrank statistic under the assumption of proportional hazards, but does not require the assumption of exponential survival distributions.

**Total number of events:**

\[
d = \left( z_{1-\frac{\alpha}{2}} + z_{1-\beta} \right)^2 \left( \frac{\theta + 1}{\theta - 1} \right)^2
\]

**Total sample size:**

\[
N = \frac{2 \left( z_{1-\frac{\alpha}{2}} + z_{1-\beta} \right)^2}{P_e + P_c} \left( \frac{\theta + 1}{\theta - 1} \right)^2
\]

where \( P_e \) and \( P_c \) are estimated using (4).

This approximation depends on the assumption of a constant ratio between the number of patients at risk in the two treatment groups prior to each event time \( r_{0j} \approx r_{1j} \) (as shown in the “heuristic proof”). When this assumption is not satisfied, the required sample sizes tend to be overestimated.

Q. When would this assumption not be satisfied?

A. When the smallest detectable difference is large.
Some examples of study design

Example I:

A clinical trial in esophageal cancer will randomize patients to radiotherapy alone (Rx A) versus radiotherapy plus chemotherapy (Rx B). The goal of the study is to compare the two treatments with respect to survival, and we plan to use the logrank test. From historical data, we know that the median survival on Rx A for this disease is around 9 months. We want 90% power to detect an improvement in this median to 18 months. Past studies have been able to accrue approximately 50 patients per year. Choose a suitable study design.
Example II:

A clinical trial in early stage breast cancer will randomize patients after their surgery to Tamoxifen (ARM A) versus observation only (ARM B). The goal of the study is to compare the two treatments with respect to time to relapse, and the logrank test will be used in the analysis. From historical data, we know that after five years, 65% of the patients will still be disease free. We would like to have 90% power to detect an improvement in this disease free rate to 75%. Past studies have been able to accrue approximately 200 patients per year. Choose a suitable study design.
Example III:

Some investigators in the environmental health department want to conduct a study to assess the effects of exposure to toluene on time to pregnancy. They will conduct a cohort study involving women who work in a chemical factory in China. It is estimated that 20% of the women will have workplace exposure to toluene. Furthermore, it is known that among unexposed women, 80% will become pregnant within a year. The investigators will be able to enroll 200 women per year into the study, and plan an additional year of follow-up at the end of accrual. Assuming they have 2 years accrual, what reduction in the 1-year pregnancy rate for exposed women will they be able to detect with 85% power? What if they have 3 years of accrual?
Other important issues:

The approaches just described address the basic question of calculating a sample size for study with a survival endpoint.

These approaches often need to be modified slightly to address the following complications:

- Loss to follow-up
- Non-compliance (or cross-overs)
- Stratification
- Sequential monitoring
- Equivalence hypotheses

Next we summarize some of the main points.
Loss to follow-up

If some patients are lost to follow up (as opposed to censored at the end of the trial without the event), the power will be decreased.

There are two main approaches for dealing with this:

- **Simple inflation method** - If \( \ell \times 100\% \) of patients are anticipated to be lost to follow up, calculate target sample size to be

\[
N^* = \left( \frac{1}{1 - \ell} \right) \cdot N
\]

**Example:** Say you calculate \( N = 200 \), and anticipate losses of 20%. The simple inflation method would give you a target sample size of \( N^* = (1/0.8) \times 200 = 250 \).

**Warning:** people often make the mistake of just inflating the original sample size by \( \ell \times 100\% \), which would have given \( N^* = 240 \) for the example above.

- **Exponential loss assumption** - the above approach assumes that losses contribute NO information. But we actually have information on them up until the time that they are lost. Incorporate this by assuming that time to loss also follows an exponential distribution, and modify \( P_e \) and \( P_c \).
Noncompliance

If some patients don’t take their assigned treatments, the power will be decreased. This issue has two sides:

- **Drop-outs** \( (d_e) \) - patients who cannot tolerate the medication stop taking it; their hazard rate would become the same as the placebo group (if included in study) at that point.

- **Drop-ins** \( (d_c) \) - patients assigned to less effective therapy may not get relief from symptoms and seek other therapy, or request to cross-over.

A conservative remedy – adjust \( P_e \) and \( P_c \) as follows:

\[
\begin{align*}
P_e^* &= P_e(1 - d_e) + P_c d_e \\
P_c^* &= P_c(1 - d_c) + P_e d_c
\end{align*}
\]
Design Strategy:

1. Decide on
   - Type I error (significance level)
   - clinically important difference (in terms of HR)
   - desired power

2. Determine the number of failures needed

3. Based on past experience
   - decide on a reasonable distribution for the controls (usually exponential)
   - estimate anticipated accrual per unit time
   - estimate expected rate of loss to follow up

   Vary the values of \( A \) and \( F \) until you get something practically feasible that gives the right number of failures.

4. Consider noncompliance, sequential monitoring, and other issues impacting sample size
Included on the next several pages is a SAS program to calculate sample sizes for survival studies. It uses several of the approaches we’ve discussed, including:

- Rubenstein, Gail and Santner (RGS, 1981)
- Freedman (1982)
- Lachin and Foulkes (1986)

A copy of this program is shown on the next several pages. The program requires entry of:

- Significance level (alpha)
- Power
- Sides (1 for one-sided test, 2 for two-sided test)
- Accrual period
- Follow up period
- Yearly rate of loss to follow-up
- Proportion randomized to experimental treatment arm
- One of the following:
  - Yearly event rate on control and experimental treatment arms
  - Yearly event rate on control arm, and the hazard ratio
  - Median time to event on control and experimental treatment arms
The SAS program rgsnew.sas

Back to Example I:

A clinical trial in esophageal cancer will randomize patients to radiotherapy alone (Rx A) versus radiotherapy plus chemotherapy (Rx B). The goal of the study is to compare the two treatments with respect to survival, and we plan to use the logrank test. From historical data, we know that the median survival on Rx A for this disease is around 9 months. We want 90% power to detect an improvement in this median to 18 months. Past studies have been able to accrue approximately 50 patients per year. Choose a suitable study design.

First, let’s write down what we know:

- desired significance level not stated, so use $\alpha = 0.05$ (assume a two-sided test)
- assume equal randomization to treatment arms (unless otherwise stated)
- desired power is 90%
- median survival on control is 9 months $\Rightarrow M_0 = 9$
- want to detect improvement to 18 months on Rx B $\Rightarrow M_1 = 18$
- Maximum accrual per year is 50 patients
We have all of the information we need to run the program, except the accrual and follow up times. We need to use trial and error to get these.

How do we pick from the feasible designs?

The first 4 designs all have 3 1/2 years total duration, since the follow-up period starts after the last patient has been accrued. The shorter the follow-up period given this fixed study duration, the more patients we have to enroll.

In some cases, it will be much more cost-effective to enroll fewer patients and follow them for longer. This corresponds to cases where the initial cost per patient is very high.

In other cases (where the initial cost per patient is lower), it will be better to enroll more patients. The median follow-up for the first 4 designs are 3, 2.5, 2.25, and 2 years, respectively. The total cost of treatment could be estimated by multiplying the number of patients by the median follow-up time.

Some prefer to keep the accrual period as short as possible, given how many patients can feasibly be enrolled. This will tend to give the smallest number of patients among the feasible designs. Which design would this correspond to?

Another issue to think about is whether the background conditions of the disease are changing rapidly (like AIDS) or are fairly stable (like many types of cancer). For the former situation, it would be best to have a study with a short duration so the results will have more interpretation.
Using the information given, there are a lot of other quantities we can calculate:

• The **hazard ratio of control to treated** is:

  \[
  \frac{\text{median}(\text{Rx B})}{\text{median}(\text{Rx A})} = \frac{18}{9} = 2
  \]

• The **hazard rates** for the two treatment arms are:

  for Rx A: \( \lambda_0 = \frac{-\log(0.5)}{\text{median}(\text{Rx A})} = \frac{-\log(0.5)}{9} = 0.0770 \)

  for Rx B: \( \lambda_1 = \frac{-\log(0.5)}{\text{median}(\text{Rx B})} = \frac{-\log(0.5)}{18} = 0.0385 \)

• The **yearly probability of an event** is:

  for Rx A: \( Pr(T < 1|\lambda_0) = 1 - e^{(-\lambda_0 t)} \)

  \[= 1 - e^{(-0.0770 \times 12)} = 0.603 \]

  for Rx B: \( Pr(T < 1|\lambda_1) = 1 - e^{(-\lambda_1 t)} \)

  \[= 1 - e^{(-0.0385 \times 12)} = 0.370 \]

What would happen above if we used time \( t \) in years (i.e., \( t=1 \)) instead of months?

What would happen if we calculated both the hazard rate and yearly event probability using time in years?
Based on a design with 2.5 years accrual and 1 year follow-up:

- The median follow-up time

\[ \text{median FU} = \frac{A}{2} + F \]

\[ = \frac{30}{2} + 12 = 27 \text{ months} \]

- The probability of an event during the entire study is:

(using the approximation in notes)

For Rx A:

\[ P_c = 1 - \exp(-\lambda_0 \times [A/2 + F]) \]

\[ = 1 - \exp(-0.0770 \times 27) = 0.875 \]

For Rx B:

\[ P_c = 1 - \exp(-\lambda_0 \times [A/2 + F]) \]

\[ = 1 - \exp(-0.0385 \times 27) = 0.646 \]

(the above numbers differ from what you’d get in the printout from the program, since it calculates the exact probability under the exponential distribution, instead of using the approximation)

In the calculations above, all of the “time” periods were in terms of months. You have to remember to keep the scale the same throughout.

To use the program, you need to translate the time scale in terms of years. So a median of 18 months survival would be entered as median=1.5.
What happens if we add loss to follow-up?

Required sample size for $A=2.5$, $FU=1$ year

Sequential Design and Analysis of survival studies

In clinical trials and other studies, it is often desirable to conduct interim analyses of a study while it is still ongoing.

Rationale:

- **ethical**: if one treatment is substantially worse than another, then it is wrong to continue to give the inferior treatment to patients.

- **timely reporting**: if the hypothesis of interest has been clearly established halfway through the study, then science and the public may benefit from early reporting.

**WARNING!!**

Unplanned interim analyses can seriously inflate the true type I error of a trial. If interim analyses are to be performed, it is ESSENTIAL to carefully plan these in advance, and to adjust all tests appropriately so the type I error is of the desired size.
How does the type I error become inflated?

Consider a two group study comparing treatments A and B.

Suppose the data are normally distributed (say $X_i \sim N(\mu_A, \sigma^2)$ in group A, and similarly for group B), so that the null hypothesis of interest is

$$H_0 : \mu_A = \mu_B$$

It is not too hard to figure out how the type I error can get inflated if a naive approach is used.

Suppose we plan to do $K$ interim analyses, and that exactly $m$ individuals will enter each treatment between each analysis. The test statistic at the $k$th analysis will be

$$Z_k = \frac{\sum_{i=1}^{k} \sum_{j=1}^{m} (X_{Ai,j} - X_{Bi,j}) / km}{\sqrt{2\sigma/km}} = \frac{\sum_{i=1}^{k} d_i / k}{\sqrt{2\sigma/km}}$$

where $d_i$ is the difference between the two group means at the $i$th analysis,

$$d_i = X_{Ai} - X_{Bi}$$

and $X_{Ai}$ and $X_{Bi}$ are the means in groups A and B of the $m$ individuals who entered in the $i$-th time period.
(naive) Interim monitoring procedure:

- Allow \( m \) patients to enter on each treatment arm (total of \( 2m \) additional patients)
- Calculate \( Z_k \) based on the current data
- Reject the null hypothesis if \( |Z_k| > z_{1-\alpha/2} \), where \( \alpha \) is the desired type I error.

The overall type I error rate for the study is:

\[
Pr(|Z_1| > z_{1-\alpha/2} \text{ or } |Z_2| > z_{1-\alpha/2} \ldots \text{ or } |Z_K| > z_{1-\alpha/2})
\]

If the test at each interim analysis is performed at level \( \alpha \), then clearly this probability will exceed \( \alpha \). The table below shows the Type I error rate if each test is done at \( \alpha = 0.05 \) for various values of \( K \):

<table>
<thead>
<tr>

<td>19.3%</td>
<td>26.6%</td>
</tr>
</tbody>
</table>

(from Lee, *Statistical Methods for Survival Data*, Table 12.9)
For survival data, the calculations become MUCH more com-
plicated since the data collected within each time interval
continues to change as time goes on!

What can we do to protect against this type I error inflation?

**Pocock Approach:**

Pick a smaller significance level (say $\alpha'$) to use at each interim
analysis so that the overall type I error stays at level $\alpha$.

A problem with the Pocock method is that even the very
last analysis has to be performed at level $\alpha'$. This tends to
be very conservative at the final analysis.

**O’Brien and Fleming Approach:**

A preferable approach would be to vary the alpha levels used
for each of the K interim analyses, and try to keep the very
last one “close” to the desired overall significance level. The
O’Brien-Fleming approach does that.
• There are several other approaches available for sequential design and analysis. The O’Brien and Fleming approach is probably the most popular in practice.

• There are many variations on the theme of sequential design. The type we have discussed here is called Group sequential analysis.
  – There are other approaches that require continuous analysis after each new individual enters the study!
  – There are also approaches where the randomization itself is modified as the trial proceeds. E.g. Ze- len’s “Play the winner rule” (New England Journal of Medicine 300, 1979, page 1242) and Ware’s “ECMO” study (Statistical Science, 4, 1989, page 298)

• Some designs allow for early stopping in the absence of a sufficient treatment effect as the trial progresses. These procedures are referred to as “stochastic curtailment” or “conditional power” calculations.
• Designing a group sequential trial for survival data requires sophisticated and highly specialized software. EaSt, a package from CYTEL SOFTWARE that does standard (fixed) survival designs, as well as sequential designs.

• Many “non-statistical” issues enter decisions about whether or not to stop a trial early.

• P-values based on analyses of studies with sequential designs are difficult to interpret.

• Once you do 5 interim analyses, then adding more makes little difference. Some clinical trials groups (HSPH AIDS group) have large randomized Phase III studies monitored at least once per year (for safety reasons), and most studies have 1-3 interim looks.

• Going from a fixed to a group sequential design adds only about 3-4% to the required maximum sample size. This is a good rule of thumb to use in calculating the sample size when you plan on doing interim monitoring.
Competing Risks and Multiple Failure Times

So far, we’ve been acting as if there was only one endpoint of interest, and that censoring due to death (or some other event) was independent of the event of interest.

However, in many contexts it is likely that the time to censoring is somehow correlated with the time to the event of interest. In general, we often have several different types of failure (death, relapse, opportunistic infection, etc) which are related (i.e., dependent or “competing” risks).

Examples:

- After a bone marrow transplantation, patients are followed to evaluate “leukemia-free survival”, so the endpoint is time to leukemia relapse or death. This endpoint consists of two types of failures (competing risks):
  - leukemia relapse
  - non-relapse deaths
- In cardiovascular studies, deaths from other causes (such as cancer) are considered competing risks.
- In actuarial analyses, we look at time to death, but want to provide separate estimates of hazards for each cause of death (multiple decrement lifetables).
Another example: For the MAC study, the analyses you have been doing of time to MAC assume that the censoring time is independent.

Recall:

\[ T = \text{time to event of interest (MAC)} \]
\[ U = \text{time to censoring (death, loss to FU)} \]
\[ X = \min(T, U) \]
\[ \delta = I(T \leq U) \]

Observable Data: \((X, \delta)\)

What are the possiblities here?

- (1) Failure \(T\) and censoring \(U\) are independent
- (2) Failure \(T\) and censoring \(U\) are dependent
Case (1): Independent failure times
(this includes the case of independent censoring)

BOTTOM LINE ⇒ NO PROBLEM

Nonparametric estimation:

In this case, we can use the Kaplan-Meier estimator to estimate $S_T(t) = P(T > t)$.

Parametric estimation:

If we know the joint distribution of $(T, U)$ has a certain parametric form (exponential, Weibull, log-logistic), then we can use the likelihood for $(X, \delta)$ to get parameter estimates of the marginal distribution of $S_T(t)$.

Semi-parametric estimation:

We can apply the Cox regression model to assess the effects of covariates on the marginal hazard.
Case (2): Dependent failure times

**BOTTOM LINE ⇒ BIG PROBLEM**

Tsiatis (1975) showed that $S_T(t) = P(T \geq t)$ (i.e., the survival function for the event $T$ of interest) cannot be “identified” from data of the form $(X, \delta)$ for each subject.

In fact, observing $(X, \delta)$ does not provide enough information to estimate the joint distribution of $(T, U)$ so that we can even check whether the assumption of independence is valid.

**When is it reasonable to assume independent risks?**

- when censoring occurs because the study ends, or because the subject moves to a different state
- and there is no trend over time in health status of enrolling patients

In the case of our MAC study, the fact that someone dies may reflect that they would have been at greater risk of MAC if they had not died than someone else who remained alive at that point.

The assumption of independence means that the hazard for someone who is censored at time $t$ is exactly the same as that for someone with the same covariates who is also at risk at time $t$. 

467
What is the impact of dependent competing risks?

Slud and Byar (1988) show that dependent causes of death can potentially make risk factors appear protective:

If we have

\[ T = \text{death from cause of interest} \]

and \[ U = \text{censoring, from death due to other cause} \]

and a single binary covariate \( Z \)

\[ Z = \begin{cases} 
1 & \text{if risk factor is present} \\
0 & \text{otherwise} 
\end{cases} \]

and we calculate the Kaplan-Meier survival estimates \( \hat{S}_1(t) \) for \( Z = 1 \) and \( \hat{S}_0(t) \) for \( Z = 0 \) assuming independent censoring, then we could (in their hypothetical example) end up reversing the sign of the survival functions:

**True ordering between survival distributions:**

\[ S_1(t) < S_0(t) \quad \text{for all } t \]

**Kaplan Meier estimates of survival distributions:**

\[ \hat{S}_1(t) > \hat{S}_0(t) \quad \text{for all } t \]
What can we do if we suspect dependent risks?

A lot of people have tried to tackle this problem!

References

There has been a lively debate in the literature about the best way to attack this problem. The two sides are basically divided about which type of model to use:

- based on cause-specific hazard functions (observables)
- based on latent variable models (unobservables)

The first approach focuses on what the observed survival is due to a certain cause of failure, acknowledging that there are other types of failures operating at the same time.

The second approach attempts to estimate what the survival associated with a certain failure type would have been, if the other types of failures had been removed.
General Case of Multiple Failure Types

In general, say we have $m$ different types of failure (say, causes of death), and the respective times to failure are:

$$T_1, T_2, T_3, \ldots, T_m$$

and we observe $T = \min(T_1, T_2, \ldots, T_m)$

We can write the cause-specific hazard function for the $j$-th failure type as:

$$\lambda_j(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} Pr(t \leq T < t + \Delta t, J = j|T \geq t)$$

The overall hazard of death is the sum over the failure types:

$$\lambda(t) = \sum_{j=1}^{m} \lambda_j(t)$$

where

$$\lambda(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} Pr(t \leq T < t + \Delta t|T \geq t)$$

Q. Can we estimate these quantities? ...even if the risks are dependent?

A. Yes, Prentice (1978) shows that probabilities that can be expressed as a function of the cause-specific hazards can be estimated.
For example, estimable quantities include:

(a) **The overall survival probability**:\(^3\)

\[
S_T(t) = P(T \geq t) = \exp \left[ - \int_0^t \lambda(u)du \right] \\
= \exp \left[ - \int_0^t \sum_j \lambda_j(u)du \right]
\]

(b) **Conditional probability of failing from cause** \(j\) **in the interval** \((\tau_{i-1}, \tau_i]\\

\[
Q(i, j) = [S_T(\tau_{i-1})]^{-1} \int_{\tau_{i-1}}^{\tau_i} \lambda_j(u) S_T(u) \, du
\]

(c) **Conditional probability of surviving** \(i^{th}\) **interval**

\[
\rho_i = 1 - \sum_{j=1}^{m} Q(i, j)
\]

\(^3\)Note: previously I said you couldn’t estimate \(S_T(t)\), but that was when \(T\) was the time to event of interest (possibly unobservable) and \(U\) was the possibly correlated censoring time. Here, \(S_T(t)\) is the survival distribution for the minimum of all failures, which can always be observed
Estimators:

(a) The MLE of $Q(i, j)$ is simply

$$\hat{Q}(i, j) = \frac{d_{ij}}{r_i}$$

i.e., the number of failures (deaths) due to cause $j$ during the $i$-th interval among the $r_i$ subjects at risk of failure at the beginning of the interval.

(b) The MLE of $\rho_i$ is:

$$\hat{\rho}_i = \frac{r_i - \sum_{j=1}^{m} d_{ij}}{r_i} = 1 - \frac{\sum_{j=1}^{m} d_{ij}}{r_i}$$

(c) The MLE of $S_T(t)$ is based on $\rho_i$:

$$\hat{S}_T(\tau_i) = \prod_{k=1}^{i} \rho_k$$
So what can’t we estimate?

Compare the cause-specific hazard function:

$$\lambda_j(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} Pr(t \leq T < t + \Delta t, J = j|T \geq t)$$

with the marginal hazard function:

$$\lambda_j(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} Pr(t \leq T_j < t + \Delta t|T_j \geq t)$$

We can get estimates of the cause-specific hazard function, since we can estimate $S_T(t) = P(T \geq t)$ even if the failure times are dependent. (In other words, we can observe whether each patient is still alive or not)

But unfortunately, we can’t estimate the marginal hazard function when the risks are dependent, since we can’t estimate $S_j(t) = P(T_j \geq t)$. (we can’t tell when they would have had event $T_j$ if they have a different event first)

This is the main tricky issue of competing risks analyses.
Back to original question...

What can we do if we suspect dependent risks?

Ex. Say we have two types of failures, $T_1$ and $T_2$, and we think they are dependent. However, we are interested in the first type of failure $T_1$, and view the competing risk $T_2$ as censoring (like in bone marrow transplant example).

Methods of summarizing data with competing risks:

1. Summarize the cause-specific hazard rate over time
2. Use the Kaplan-Meier estimate anyway, $\hat{S}_{T_1}(t)$
3. Report the complement to the KM, $1 - \hat{S}_{T_1}(t)$
4. Use cumulative incidence curves (crude incidence curve)
5. Use the conditional probability function
6. Give upper and lower bounds for the true marginal survival function, in the absence of the competing risk

Pepe and Mori review the first 5 of these options, and recommend against option (2), but note that this is often what people end up doing.
To make the example more concrete:

Say we are interested in time to MAC or death, whichever occurs first. We define:

\[ T = \text{time to MAC or death} \]
and\[ U = \text{censoring (assumed independent)} \]

and the type of failure is denoted by \( j \)

\[ j = \begin{cases} 
M & \text{if event is MAC} \\
D & \text{if event is death from other causes}
\end{cases} \]

In the alternative “latent variable” framework, we would define

\[ T_M = \text{time to MAC} \]
and \[ T_D = \text{time to Death} \]

although we might not be able to observe \( T_M \) if \( T_D \) occurred first.
Methods for competing risks:
(1) Summarizing the cause-specific hazard over time

As mentioned above, this is one of the quantities that we can estimate. Our basic estimator during time interval $i$ is

$$\hat{Q}(i, j) = \frac{d_{ij}}{r_i}.$$ 

So we can plot $\hat{\lambda}_j(t)$ over time, and get some insight as to biological phenomena involved.

However, if you remember some of the plots I showed you of hazards over time, they tended to be highly variable. Several contributions have been made towards “smoothing” out the inherent variability in the estimates of cause-specific hazards.

- Efron (1988)
- Ramlau-Hansen (1983)
- Tanner and Wong (1983)

**Drawback:** the hazard functions alone do not give overall effect of a covariate on survival.

**Example:** If the hazard functions for $\lambda_j(t)$ for two treatments cross, we can’t say which treatment leads to lower overall event rate.
Figure from Pepe and Mori for Leukemia Data
Kernel Estimates of Cause-Specific Hazards
Methods for competing risks:
(2) Applying Kaplan-Meier to cause-specific $\lambda_j$’s

Say we evaluate the MAC survival distribution by treating
- all MAC cases as “events”
- any deaths without MAC as “censorings”

and construct the Kaplan-Meier survival curve.

What are we estimating?

$$S_M^*(t) = \exp\left[-\int_0^t \lambda_M(u) \, du\right]$$

where $\lambda_M(t)$ is the cause-specific hazard for MAC:

$$\lambda_M(t) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \Pr(t \leq T < t + \Delta t, j = M|T \geq t)$$

i.e., the conditional probability that MAC occurs in a short period of time, given that the subject is *alive* and *MAC-free*.

The interpretation of the Kaplan-Meier curve is as the

“exponential of the negative cumulative cause-specific hazard”.

Clinicians (and others!) have difficulty understanding this function, since it has no direct clinical interpretation.
They thought this was such a bad idea, that they did not include any plot of this!
Methods for competing risks:
(3) Using the complement of the Kaplan-Meier

Another function used fairly often in the competing risks area is sometimes referred to as the pure probability function:

$$1 - S_j^*(t) = 1 - \exp \left[ - \int_0^t \lambda_j(u) \, du \right]$$

In our MAC example, $1 - S_M^*(t)$ could be interpreted as the predictive probability of MAC by time $t$ if the risk of death could be removed.

If we were designing a new study for a miracle drug that seemed so powerful that it would not only reduce MAC but prevent all death from other causes in HIV-infected patients, then we could use estimates $1 - \hat{S}_M^*(t)$ to help design our new study.

This would be pretty optimistic, and there has been a lot of work on the strict (and untestable) assumptions required to interpret the KM curve in this manner.

Pepe and Mori contend that this function is irrelevant for summarizing data from a competing risks study.
Figure from Pepe and Mori for Leukemia Data Complement Kaplan-Meier Functions

SUMMARIZING COMPETING RISKS FAILURE TIME DATA

Relapse: $1 - \hat{S}_R(t)$

Non-relapse death: $1 - \hat{S}_{DR}(t)$

Figure 1. Complement Kaplan–Meier functions
Methods for competing risks:
(4) Using Cumulative Incidence Curves

This has also been termed the “crude incidence curve”, and estimates the marginal probability of an event in the setting where other competing risks are acknowledged to exist.

Description of Method: the method is described in more detail in Kalbfleisch and Prentice (p.169).

Tests for covariates: Tests for comparing cumulative incidence curves among treatment groups (or some other covariate) have been developed by Bob Gray (1988). They are similar to logrank tests in that they are “linear rank” statistics.

If we were able to follow up all subjects to time $t$, then the cumulative incidence curves would reflect what proportion of the total study population have had the particular event (i.e., MAC) by time $t$. 
Figure 3. Marginal probability functions. Cumulative incidence estimates were used.
Methods for competing risks:
(5) Conditional Probability Curves

This has the same flavor as the complement KM, but a more natural interpretation. Pepe and Mori define the conditional probability function as:

\[ \hat{CP}_M(t) = P(T_M \leq t | T_D \geq t) \]
\[ = \frac{\hat{P}_M(t)}{1 - \hat{P}_D(t)} \]

where \( \hat{P}_M(t) = \int_0^t \hat{S}_T(u) \frac{dN_M(u)}{Y(u)} \)

and \( \hat{P}_D(t) = \int_0^t \hat{S}_T(u) \frac{dN_D(u)}{Y(u)} \)

In the above, \( \hat{S}_T(u) \) is the KM estimate of the overall mac-free survival distribution, and the terms \( N_M(u), N_D(u), \) and \( Y(u) \) reflect the “counting process” for the number of subjects with MAC, death, and at risk at time \( u \), respectively.

In the absence of censoring, the interpretation is the proportion of patients who develop MAC among those who do not die of other causes.

Tests: Pepe and Mori also present tests, which are sums over time of weighted differences between the conditional (or marginal) probabilities for two groups.
Figure from Pepe and Mori for Leukemia Data
Conditional Probability and Marginal Curves
Methods for competing risks:
(6) Bounds on Net Survival Curves

As noted previously, we cannot estimate $S_j(t) = P(T_j \geq t)$ if the failure times are dependent (eg, we can’t estimate the survival function for MAC if time to MAC is correlated with time to death without MAC).

However, we may be able to say something about the range of $S_j(t)$ by finding upper and lower bounds that contain $S_j(t)$.

- **Peterson** (1976) obtained general bounds based on the minimal and maximal dependence structure for $(T_M, T_D)$. The bounds allow any possible dependence structure, but can be very wide.

- **Slud and Rubenstein** (1983) obtained tighter bounds on $S_j(t)$ by using additional information, but require the user to specify reasonable bounds on a function $\rho$. Once $\rho$ is supplied, the marginal distribution $S_{j,\rho}(t)$ can be obtained.

- **Klein and Moeshberger** (1988) use the framework of Clayton and Oakes for bivariate survival to obtain tighter bounds than those of Peterson. Again, the user has to supply bounds on a function $\theta$, and once this is given $\hat{S}_{j,\theta}(t)$ can be obtained.

Bounds on Net Survival Curves

Figure 2. Bounds on survival for non-Hodgkins lymphoma patients.
One last example: Promotion of Faculty at HSPH

I was asked to analyze the school’s data from 1980-1995 on promotion of Faculty from Assistant Professor to Associate Professor to assess whether there were differences between males and females and among academic areas (social, laboratory, quantitative).

Problem:
Would you think that “censoring” (someone leaving their tenure track position prior to getting promoted) is independent of the probability of promotion?

I considered 3 approaches for accounting for censoring:

Method I: assumes those who departed would NOT have been promoted

Method II: assumes those who departed would have been promoted at the same rate as those who stayed

Method III: assumes 50% of those who departed would not have been promoted, and the other 50% would have been promoted at the same rate as those who stayed

Which Method corresponds to “non-informative” (independent) censoring?
Results: Cumulative probabilities of promotion
